ROBUST AND EFFICIENT ADAPTIVE ESTIMATION OF BINARY-CHOICE REGRESSION MODELS

By Pavel Čižek

February 2007
Robust and Efficient Adaptive Estimation of Binary-Choice Regression Models

Pavel Čížek

The binary-choice regression models such as probit and logit are used to describe the effect of explanatory variables on a binary response variable. Typically estimated by the maximum likelihood method, estimates are very sensitive to deviations from a model, such as heteroscedasticity and data contamination. At the same time, the traditional robust (high-breakdown point) methods such as the maximum trimmed likelihood are not applicable since, by trimming observations, they induce the separation of data and non-identification of parameter estimates. To provide a robust estimation method for binary-choice regression, we consider a maximum symmetrically-trimmed likelihood estimator (MSTLE) and design a parameter-free adaptive procedure for choosing the amount of trimming. The proposed adaptive MSTLE preserves the robust properties of the original MSTLE, significantly improves the finite-sample behavior of MSTLE, and additionally, ensures asymptotic efficiency of the estimator under no contamination. The results concerning the trimming identification, robust properties, and asymptotic distribution of the proposed method are accompanied by simulation experiments and an application documenting the finite-sample behavior of some existing and the proposed methods.

JEL classification: C13, C20, C21, C22

Keywords: asymptotic efficiency, binary-choice regression, breakdown point, maximum likelihood estimation, robust estimation, trimming

1. INTRODUCTION

Binary-choice regression models, such as probit and logit, are frequently used in statistic and econometric applications. These models are used to describe the effect of explanatory variables \( \mathbf{x}_i \) on a binary response \( y_i \in \{0, 1\} \); most usually, the probability \( P(y_i = 1 | \mathbf{x}_i) \) is modelled as \( F(\mathbf{x}_i^\top \beta) \), where \( F \) is referred to as a link function. For example, applications of the binary-choice models include estimating probability of a firm’s bankruptcy or a disease diagnosis and modeling of decisions to work, to retire, or to have children. Such models are typically estimated by the maximum likelihood estimator (MLE) because of its asymptotic efficiency under a parametric model. On the other hand, MLE is very sensitive to atypical data: if there are misclassified observations with large values of covariates, MLE estimates can be severely biased (Croux et al. 2002). This can happen, for example, when a model does not account for all features of data (e.g., by missing some variables, by not accounting for or misspecifying of heteroscedasticity and misclassification) or data come from a heavy-tailed distribution. The first attempts to fix this sensitivity of MLE stem from Pregibon (1981), followed by Copas (1988), Carrol and Pederson (1993), Christmann (1994), Bianco and Yohai (1996), Kordzakhia et al. (2001), Croux and Haesbroeck (2003), Müller and Meykov (2003), and Gervini (2005), for instance. Our aim is to propose an alternative to these methods that, on the one hand, improves upon their robustness to atypical data (which badly influence MLE) and that, on the other hand, is asymptotically efficient as MLE if data followed the assumed model and are free of erroneous observations.
A predominant approach in making MLE more robust in the context of binary-choice regression is based on M-estimation: one replaces the likelihood function (or its score) by another function of explanatory variables $x_i$, which increases with $x_i$ at a slower rate or is even bounded. As noted by Carroll and Pederson (1993), for instance, such a change can make estimates asymptotically biased and a bias-correction term has to be included in the objective function (Bianco and Yohai 1996). The form of the correction term depends on the link function $F$ used and it might be difficult to obtain for generalizations of the binary-choice model accounting for heteroscedasticity or misclassification (e.g., Hausman et al. 1998). Additionally, a weighting function $w(x_i)$ is sometimes introduced to diminish or eliminate influence of observations with large values of covariates since the M-estimators are also sensitive to misclassified observations with extreme value of explanatory variables (Croux and Haesbroeck 2003; Gervini 2005). Such (down-)weighting of observations is however done irrespectively of their influence on the model.

Another class of robust (high-breakdown point) methods that form an alternative to M-estimation are estimators based on trimming of individual observations from the objective function; for example, the nonlinear least trimmed squares (Stromberg and Ruppert 1992; Čížek 2005) and the maximum trimmed likelihood (MTLE; Müller and Neykov 2003). These methods are however not applicable in binary-response models since, by trimming observations, they induce the separation of data and thus non-identification of parameter estimates (Albert and Anderson 1984; Čížek 2006). The only exception are data sets containing large strata, where the number of observations at any observed point $x_i$ grows with sample size (Christmann 1994).

Here we propose a new robust estimator of binary-choice models, which is highly robust without model-unrelated downweighting of observations, which is consistent
even without any bias-correction terms (and thus widely and easily applicable),
and which is additionally asymptotically efficient under the model. The proposed
estimator relies on the maximum symmetrically-trimmed likelihood estimator (MS- TLE) proposed by Čížek (2006), which is a generally applicable robust estimator of binary-choice regression with relatively poor finite-sample performance (asymptotic results are not available with the exception of consistency). To improve its finite-sample behavior, we complement MSTLE by a data-adaptive procedure for the selection of trimming proportion based on the average likelihood criterion. Further, we derive the asymptotic distribution of the adaptively-trimmed MSTLE and show that the proposed estimator is asymptotically efficient while preserving the robust properties of the original MSTLE. Although the adaptive MSTLE is discussed here within the framework of the parametric MLE estimation, the concept is straightforward to extend to parametric models with more complex parametric forms and heteroscedasticity and to semiparametric single-index models and estimators (e.g., Klein and Spady 1993).

In the rest of this paper, we first introduce main concepts and definitions in
Section 2. Further, we discuss conditions under which the proposed method is
identified and asymptotically normal in Section 3, where both robust and asymptotic
properties of the proposed adaptive MSTLE are derived. Finally, we compare the
proposed and some existing methods using Monte Carlo simulations and real data
in Section 4. Proofs are provided in Appendix B.

2. BINARY-CHOICE MODEL AND ITS ESTIMATION

Let us now introduce the model and concepts used in the paper. First, the model
and its MLE estimation is discussed. Next, we describe the existing MTLE method
(Section 2.1) and propose the adaptive MSTLE estimator (Section 2.2).

The most frequently used binary-choice regression models characterize the conditional expectation of a binary response \( y_i \in \{0, 1\} \) conditional on explanatory variables \( x_i \in \mathbb{R}^p \) as a function of a linear combination (index) of \( x_i \):

\[
P(y_i = 1|x_i) = F(x_i^\top \beta),
\]

where \( F \) is a link function (e.g., the standard normal distribution function \( \Phi \) for probit) and \( \beta \in \mathbb{R}^p \) is a vector of unknown parameters. Within this paper, the link function \( F \) is assumed to be a known non-decreasing function, although extensions to semiparametric models with an unknown monotonic function \( F \) are possible.

For a known link function \( F \), model (1) is typically estimated by MLE, which is defined by

\[
\hat{\beta}^{(MLE)} = \arg \max_{\beta \in B} \sum_{i=1}^{n} l(y_i, x_i; \beta),
\]

where \( B \) represents the parameter space and the log-likelihood contributions are

\[
l(y_i, x_i; \beta) = y_i \ln F(x_i^\top \beta) + (1 - y_i) \ln \{1 - F(x_i^\top \beta)\}.
\]

This estimator is identified only if there is an overlap in data; that is, if the two parts of data given by the values of the response variable, \( \{x_i|y_i = 1\} \) and \( \{x_i|y_i = 0\} \), are not separated in the space of explanatory variables (Albert and Anderson 1984).

MLE is asymptotically normal and efficient, but it can behave rather poorly if data are contaminated by outliers; for example, if data contain misclassified observations with large values of explanatory variables. This can be documented using one of the (global) measures of an estimator’s sensitivity to atypical data – the breakdown point. It can be defined as the largest fraction \( m/n \) of observations that can be
added at arbitrary locations without making the estimator “useless”; and naturally, adding then \( m + 1 \) observations in a right way can make the estimator “useless”. An estimator is considered useless if it does not depend on sample data anymore, that is, if it is a non-random constant (Genton and Lucas 2003). (Note that we introduced the so-called additive breakdown point instead of more usual replacement breakdown point, which is not informative in the binary-choice regression, see Christman 1994.) In the case of binary-choice regression and MLE, the MLE estimates can become zero independently of sample data if only \( 2p \) outliers are added (Croux et al. 2002). Hence, the breakdown point of MLE is bounded by \( 2p/n \) and approaches zero as \( n \to \infty \).

2.1. Maximum trimmed likelihood

The lack of robustness of MLE gave rise to more robust alternatives, mostly based on \( M \)-estimators (e.g., Carroll and Pederson 1993; Bianco and Yohai 1996; Gervini 2005), which however require asymptotic bias-corrections to achieve consistency and model-independent downweighting of observations to achieve robustness (e.g., Croux and Haesbroeck 2003; Gervini 2005). In models with continuous response, there is another high-breakdown point method derived from the MLE criterion: the maximum trimmed likelihood estimator (MTLE). For a sample \((x_i, y_i)_{i=1}^n\), MTLE is defined by (Hadi and Luceno 1997)

\[
\hat{\beta}^{(MTLE,h_n)} = \arg \max_{\beta \in B} \sum_{j=n-h_n+1}^n l_{[j]}(x_i, y_i; \beta), \quad (4)
\]

where \( l_{[j]}(x_i, y_i; \beta) \) represents the \( j \)th order statistics of likelihood contributions \( l(x_i, y_i; \beta), i = 1, \ldots, n \), and \( h_n \) is the trimming constant, \( n/2 < h_n \leq n \). Compared to MLE, the \( n - h_n \) observations with smallest likelihood values, that is, least
probable observations under a given model, are left out of the likelihood function. This intuitively indicates that the breakdown of MTLE should be close to \((n-h_n)/n\), which can asymptotically approach \(1/2\) if \(h_n = \lfloor n/2 \rfloor + 1\) (\([x] \) represents the integer part of \(x\)). The robust properties of MTLE were studied in the linear and generalized linear regression models by Vandev and Neykov (1998) and Müller and Neykov (2003), respectively.

The trimmed estimators such as MTLE are however not applicable in the binary-choice model (1) unless the number of observations at any observed point \(x_i\) grows with sample size (Christmann 1994), that is, unless all variables are discrete. One reason is the non-identification of parameters if a large proportion of data, for example \(h_n = \lfloor n/2 \rfloor + 1\), is trimmed from the objective function: intuitively, splitting sample to parts where responses \(y_i = 1\) or \(y_i = 0\) are more likely, \(S_k = \{(y_i, x_i)|P(y_i = k|x_i) \geq 0.5\}\) for \(k = 1\) and \(k = 0\), respectively, there are generally less observations with response \(y_i = 1 - k\) than with response \(y_i = k\) in \(S_k, k = 0, 1\); at the same time, observations with response value \(y_i = 1 - k\) in \(S_k\) are less probable than observations with \(y_i = k\) in \(S_k\); consequently, all observations in \(S_k\) with response \(y_i = 1 - k\) will be trimmed from the objective function (4) and only two separated groups of observations without overlap will be kept in (4), which causes the non-identification of parameters. See Christmann and Rousseeuw (2001) and Čížek (2006) for details.

2.2. Adaptive maximum symmetrically-trimmed likelihood

To adapt the trimmed estimators to the binary-choice models, Čížek (2006) introduced the maximum symmetrically-trimmed likelihood estimator (MSTLE), which
trims observations independently of the response values \( y_i \):

\[
\hat{\beta}^{(\text{MSTLE},h_n)} = \arg \max_{\beta \in B} \sum_{j=1}^{n} l(x_i, y_i; \beta) \cdot I\left( r(x_i; \beta) \geq r_{[n-h_n+1]}(x_i; \beta) \right), \tag{5}
\]

where \( r(x_i; \beta) = \min_{y \in \{0,1\}} l(x_i, y; \beta) \). Consequently, MSTLE trims observations \((y_i, x_i)\) such that one of responses is improbable, be it \( y_i = 1 \) or \( y_i = 0 \). Since MSTLE cannot trim just observations with \( y_i = 1 \) or just with \( y_i = 0 \), it does not create a separation of data and parameters are identified (see Čížek 2007, Section 4.3, for details).

The MSTLE estimator is a robust positive breakdown-point method, but contrary to the estimation of continuous-response models, the breakdown point of MSTLE cannot asymptotically exceed \( 1/3 \) (Čížek 2006). This can be achieved for \( h_n = [(2n)/3] \) (smaller values of \( h_n \) are possible, but do not lead to an increase of the breakdown point). Furthermore, the symmetric trimming eliminates observations with \( P(y_i|x_i) \) close to 0 or 1, which can significantly influence the estimator if they are misclassified, but which are best fit by the model if they are correct. Hence, the variance of MSTLE estimates is rather large unless \( h_n \) is close to \( n \).

As a remedy, we propose a data-adaptive procedure to determine the amount of trimming so that observations are not trimmed unnecessarily. In this context, the key observation is that, due to the monotonicity of the link function \( F \), the average log-likelihood of non-trimmed observations increases with \( h_n \) under the model (1).

**Lemma 1** Let \((x_i, y_i)\) be a random vector, \( F \) a non-decreasing link function, and \( \beta_0 \in \mathbb{R}^p \) the underlying parameter value such that the expectation \( E l(x_i, y_i; \beta_0) \) is finite. Then it holds that \( E \left[ l(x_i, y_i; \beta_0) \right| r(x_i; \beta_0) \geq C \] is non-increasing in \( C, C < 0 \), and hence,

\[
E \left[ l(x_i, y_i; \beta_0) \right| r(x_i; \beta_0) \geq r_{[n-h_n+1]}(x_i; \beta_0) \right] \]

8
is non-decreasing in $h_n$ for any given sample size $n \in \mathbb{N}$.

Consequently, if there are no influential misclassified observations, MSTLE estimates for all values of trimming constant $h_n$ will be consistent, close to the true parameter value $\beta_0$, and by Lemma 1, the average log-likelihood of non-trimmed observations will increase with $h_n$. On the other hand, if there are influential misclassified observations, the parameter estimates become biased (usually towards zero) once $h_n$ is sufficiently large so that the misclassified observations are not trimmed from the objective function (5). Subsequently, the property derived in Lemma 1 will not apply anymore.

The above stated observation motivates the following data-adaptive procedure. Select a grid $2/3 = \lambda_1 < \ldots < \lambda_M = 1$ of $M$ points, where $M \in \mathbb{N}$ is fixed. For each $m = 1, \ldots, M$, define $h^*_m = [\lambda_m n]$ and perform the corresponding MSTLE estimation, which results in an estimate $\hat{\beta}^m$ and the maximal symmetrically-trimmed likelihood value $L^m_n$ from (5). Next, select $m^*_n$ maximizing the average log-likelihood $L^m_n / h^*_m$,

$$m^*_n = \arg \max_{m=1,\ldots,M} \frac{1}{h^*_m} \sum_{j=1}^n l(x_i, y_i; \hat{\beta}^m) \cdot I\left(r(x_i; \hat{\beta}^m) \geq r_{[n-h^*_m+1]}(x_i; \hat{\beta}^m)\right).$$

Finally, define the adaptive MSTLE estimator as $\hat{\beta}^{(AMSTLE)} = \hat{\beta}^{m^*_n}$, which corresponds to the MSTLE estimator using the trimming constant $h^* = h^*_{m^*_n}$. (Note that one could theoretically perform an optimization over all $h_n$, $2n/3 \leq h_n \leq n$, which would however be computationally impractical.)
In this section, the robust and asymptotic properties of the proposed adaptive MSTLE estimator will be studied. Let us therefore introduce first the assumptions concerning the model (1) and the random variables $x_i$ and $y_i$. The below stated assumptions have to be accompanied by some further regularity assumptions that are summarized in Appendix A.

Assumptions

1. Let the link function $F(z)$ be a strictly increasing and twice continuously differentiable function on its support $\{z|0 < F(z) < 1\}$ and let $F(0) = 1/2$. Moreover, functions $\ln F(z)$ and $\ln\{1 - F(z)\}$ are assumed to be concave.

2. Let random variables $\{y_i, x_i\}_{i \in \mathbb{N}}$ form an identically distributed absolutely regular sequence of random vectors with finite second moments. Further, let $E(x_i x_i^\top)$ be a positive definite matrix.

3. The distribution function $G_\beta$ of $F(x_i^\top \beta)$ is assumed to be absolutely continuous with a density function $g_\beta$, which is positive on its support and uniformly bounded over a neighborhood $\beta \in U(\beta_0, \delta)$ for some $\delta > 0$.

First, note that the assumptions concerning the link function $F$, especially the monotonicity and concavity of its logarithm, are sufficient conditions for the existence and uniqueness of MLE (Silvapulle 1981); assumption $F(0) = 1/2$ just identifies the intercept in binary-choice regression. Next, the assumptions concerning the random variables $x_i$ and $y_i$ allow for a dependence across observations. At the same time, some of the variables (with non-zero coefficients) have to be continuously distributed so that the regression function $F(x_i^\top \beta_0)$ is continuously distributed. This
is however not an important limitation: if all explanatory variables are discrete, any location estimator can be applied and no specific method is necessary (e.g., Christmann 1994).

3.1. Breakdown point

As indicated in Section 2.2, the breakdown point of MSTLE can be (asymptotically) at most 1/3, but in general, it depends on the data generating process (this is typical especially for nonlinear models and under dependency, Genton and Lucas 2003). Thus for a given model and sample, let \( \varepsilon_{m} \) denote the breakdown point of the MSTLE estimator using the trimming constant \( h_{m} = [\lambda_{m}n] \), \( m = 1, \ldots, M \). We will now show that the adaptive MSTLE method preserves the breakdown properties of the original MSTLE.

**Theorem 1** For a sample of size \( n \), consider a grid \( \frac{2}{3} = \lambda_{1} < \ldots < \lambda_{M} = 1 \) of \( M \) points, the MSTLE estimators defined by trimming constants \( h_{m} = [\lambda_{m}n] \), \( m = 1, \ldots, M \), and the corresponding breakdown points \( \varepsilon_{1}, \ldots, \varepsilon_{M} \). Under Assumption 1, the breakdown point \( \varepsilon_{a} \) of the adaptive MSTLE estimator then equals to \( \varepsilon_{a} = \max_{m=1,\ldots,M} \varepsilon_{m} \) at any sample of size \( n \), where MLE is identified.

Theorem 1 confirms that the breakdown point of the adaptive MSTLE procedure is equal to the breakdown point of MSTLE with the most robust choice of the trimming constant. Thus, the adaptive choice of trimming does not adversely influence the breakdown properties of MSTLE.

3.2. Asymptotic distribution

Although the adaptive MSTLE does not lose the robust properties of the original MSTLE method, it is crucial that it improves the quality of estimation (e.g., the
variance of estimates), especially if data do not contain any influential or atypical observations. Therefore, the asymptotic distribution of MSTLE is derived first. Later, we focus on the adaptive estimation using data generated from model (1) and prove that the adaptive MSTLE is asymptotically efficient.

The asymptotic distribution of MSTLE can be derived using the results of Čížek (2007) on the general trimmed estimation.

**Theorem 2** Under Assumptions 1–8, the MSTLE estimator \( \hat{\beta}_{MSTLE,h_n} \), where \( h_n = [\lambda n] \) and \( 0 < \lambda \leq 1 \), is asymptotically normal; that is, \( \sqrt{n}(\hat{\beta}_{MSTLE,h_n} - \beta_0) \to N(0, V) \) in distribution as \( n \to \infty \).

Note that the above result concerning the asymptotic normality of MSTLE does not specify the precise form of the asymptotic variance. Even though it can be formally derived, it does not have a computationally feasible form (see Čížek 2007). Hence, it has to be computed by a parametric or a robust nonparametric bootstrap, for instance (e.g., Hall and Presnell 1999; Salibian-Barrera and Zamar 2002).

Now, considering the adaptive MSTLE procedure performed on a grid \( \Lambda = (\lambda_1, \ldots, \lambda_M) \), the asymptotic distribution is determined by the chosen level of trimming. Provided that the average log-likelihood at the true parameter value,

\[
E \left[ l(x_i, y_i; \beta_0) | r(x_i; \beta_0) \geq r_{[n-h_n+1]}(x_i; \beta_0) \right] ,
\]

has a unique minimum on \( \Lambda \), say at \( \lambda_s \), the optimal amount of trimming \( \lambda_{m_n} \) will converge in probability to \( \lambda_s \), \( \lambda_{m_n} \to \lambda_s \) as \( n \to \infty \). Consequently, the asymptotic distribution of the adaptive MSTLE will be equivalent to the one of MSTLE with trimming equal to \( h_n = [\lambda_s n] \). A particular case of this general conjecture for data without any contamination is derived in the following theorem.
Theorem 3 Consider a grid $2/3 = \lambda_1 < \ldots < \lambda_M = 1$ of $M$ points and the MSTLE estimators defined by $h_m^n = [\lambda_m n]$, $m = 1, \ldots, M$. Under Assumptions 1–8, the adaptive MSTLE estimator $\hat{\beta}^{(AMSTLE)}$ has the same asymptotic distribution as the MLE estimator of the same model. Specifically as $n \to \infty$, $m_n^* \to M$ in probability, $\lambda_m^* \to 1$ in probability, and finally, $\sqrt{n}(\hat{\beta}^{(AMSTLE)} - \beta_0) \to N(0, V^{MLE})$ in distribution, where $V^{MLE}$ denotes the asymptotic variance of MLE.

The most important consequence of Theorem 3 is that, for data described by model (1), the adaptive MSTLE procedure selects the correct amount of trimming, $\lambda = 1$, and additionally, this selection does not influence the asymptotic distribution of the estimator (at least up to the order $\sqrt{n}$). Hence, the adaptive MSTLE is asymptotically efficient.

4. FINITE-SAMPLE PROPERTIES

To compare the performance of various methods for estimating binary-choice regression models in finite samples, Monte Carlo simulations (Sections 4.1 and 4.2) and a real data set (Section 4.3) are used. In this section, we compare the proposed MSTLE and adaptive MSTLE (AMSTLE) methods with MLE and the Bianco and Yohai (1996) estimator (BYE), which is based on a bias-corrected M-estimator and was implemented by Croux and Haesbroeck (2003). We also consider weighted forms of MLE and BYE, denoted WMLE and WBYE, respectively. They are based on weights defined by $w_i = I(RD_i^2 \leq \chi^2_{p,0.075})$, where $\chi^2_{p,0.975}$ denotes the 97.5\% quantile of $\chi^2$ distribution with $p$ degrees of freedom and $RD_i$ represents the Mahalanobis distance of observation $x_i$ based on a robust estimate of location and covariance (see Croux and Haesbroeck 2003 for details). Such a choice of weights, which depend just on the position of observations in the space of explanatory variables and down-

weight all distant observations, is frequently used in the case of M-estimators (e.g., Gervini 2005).

As BYE is currently implemented only for logit, we compare all methods using a logistic model. In the case of simulated data, we generate $p$ explanatory variables $x_1, \ldots, x_p \sim N(0, 1)$, and for a given parameter vector $\beta = (\beta_0, \beta_1, \beta_2, 0, \ldots, 0)^\top$, we define $y = I(\beta_0 + \beta_1 x_1 + \beta_2 x_2 + \varepsilon \geq 0)$, where $\varepsilon \sim \Lambda(0, 1)$ ($N(\mu, \sigma)$ and $\Lambda(\mu, s)$ refer to the Gaussian and logistic distributions, respectively). If a generated data set is not further modified, we refer to it as CLEAN. Next, to examine robust properties of all estimators, we also use contaminated data: a given fraction $\alpha \in (0, 1)$ of observations is shifted by $(\Delta_1, \Delta_2) \in \mathbb{R}^2$ and misclassified, which corresponds to transformations $x_1^* = x_1 + \Delta_1, x_2^* = x_2 + \Delta_2$, and $y^* = I(\beta_0 + \beta_1 x_1^* + \beta_2 x_2^* < 0)$. Such data sets are referred to as OUTLIERS($\alpha; \Delta_1, \Delta_2$).

Finally, let us note that the simulated results discussed in this section are obtained for $\beta_0 = 0.5, \beta_1 = 1$, and $\beta_2 = -1$ using sample sizes $n = 100, 200, 400$ and 500 simulations. The MSTLE estimator is computed using the trimming constant $h_n = [0.75n]$ and the adaptive MSTLE estimator chooses the trimming parameter $\lambda \in \{0.66, 0.70, 0.75, 0.80, 0.85, 0.90, 0.95, 1.00\}$.

4.1. Estimation with no contamination

The performance of all methods is first analyzed for data CLEAN, which are not contaminated by misclassified observations. The absolute values of bias and mean squared error (MSE) for each method are recorded in Table 1. For such data, MLE is the optimal estimation method as is confirmed by the simulations at all sample sizes: both the bias and MSE of MLE are minimal. The performance of MLE is closely matched by its weighted form and also by the (W)BYE estimators. On the other hand, MSTLE exhibits both a sizeable bias and large MSE (as expected). In contrast to this, the adaptive MSTLE is, in terms of MSE, slightly worse than (W)MLE and (W)BYE for $n = 100$, outperforms all methods but MLE for $n = 200$, and becomes identical to MLE at $n = 400$. The behavior of all methods is similar also for a more complex model with $p = 12$ variables, see Table 5 in Appendix C.

4.2. Estimation under contamination

All methods are now compared for contaminated data sets, where 5% observations are misclassified distant observations. Two cases, OUTLIERS(0.05; 1.5, -1.5) and
Table 3: Bias and MSE of all methods for data OUTLIERS(0.05; 5.0, -5.0) using $p = 2$ variables and sample sizes $n = 100, 200, \text{ and } 400$.

OUTLIERS(0.05; 5.0, -5.0), are considered that differ by the distance of outlying observations from the rest of the data. We refer to the two cases as data with near outliers and data with distant outliers, respectively. The absolute values of bias and mean squared error (MSE) for both experiments are in Tables 2 and 3, respectively.

In the case of data with near outliers, the MSE of all methods, but MSTLE, are similar at $n = 100$, although their large values have different sources – large bias in the cases of (W)MLE and (W)BYE and large variance in the case of the adaptive MSTLE. As the sample size increases, the biases and MSEs of (W)MLE and (W)BYE remain approximately on the same levels, whereas both measures significantly decrease in the case of (A)MSTLE. The adaptive MSTLE is thus the best performing method in this case since WMLE and WBYE are not able to detect and withstand this type of contamination at all.

The situation is different in the case of data with distant outliers. Even though MLE and BYE are extremely biased, their weighted versions WMLE and WBYE exhibit relatively small bias and MSE because the outlying points are now severely downweighted due to their distance from the rest of the data in the space of the explanatory variables. The adaptive MSTLE method, that does not a priori remove
Figure 1: Data on 33 leukemia patients; symbol ‘+’ represents AG positive patients, whereas ‘◦’ stands for AG negative patients.

observations due to their position in the space, performs worse than WMLE at \( n = 100 \), but closely matches the performance of the weighted methods at \( n = 200 \), and slightly outperforms WMLE and WBYE at \( n = 400 \).

The presented simulation results are representative also for higher levels of contamination (see Tables 7 and 9 in Appendix C) as well as for models with more explanatory variables (see Tables 6 and 8 in Appendix C).

4.3. Application

Let us now compare the (W)MLE, (W)BYE, and adaptive MSTLE using data on 33 leukemia patients. This data set, studied for example by Cook and Weisberg (1992)
Table 4: Parameter estimates by all methods for the leukemia data. Estimate MLE(-15) represents the MLE estimate for the data without the 15th observation.

and Kordzakia et al. (2001), indicate whether a patient survives longer than one year (dependent variable $y_i = 1$) conditional on the white blood cell count (measured in thousands, variable WBC) and a dichotomous morphological factor AG. Data are depicted on Figure 1, where we can observe that the chance to survive more than one year decreases with high values of WBC. Moreover, there is one extreme data point (observation 15) for a patient living longer than one year despite his WBC value being equal to 100 (other AG positive patients with WBC values above 50 did not survive longer than 5 weeks; see Feigl and Zelen 1965). This could possibly be due to some other unobservable physiological conditions of that particular patient.

To provide a benchmark for comparing various estimators, we compute the MLE estimates both for the whole data and for data without the 15th observation. Together with (W)MLE, (W)BYE, and the adaptive MSTLE, all estimates are presented in Table 4. The corresponding standard errors are obtained by a parametric bootstrap (using 10000 replications) because of the small sample size.

First, let us observe that, for the parameter WBC, the MLE estimate based on all data is more than 7 times smaller than the MLE estimate after omission of the 15th observation. Next, the WMLE and adaptive MSTLE with adaptively chosen
trimming \( h^* = 31 = [0.95 \cdot 33] \) provide the same estimates as MLE after omitting the 15th observation, although they have slightly smaller of WBC estimate. Note that rather small standard errors of the adaptive MSTLE relative to results previously achieved in simulations likely come from the fact that trimming occurs here only on one side of data, that is, for large values of WBC (see Figure 1). Finally, although the WBYE estimates are rather close to those by WMLE and adaptive MSTLE, both BYE and WBYE seem to exhibit a downward bias since all their coefficients are 0.75 and 0.94 multiples of (W)MLE, respectively.

5. CONCLUSION

The adaptive maximum symmetrically-trimmed likelihood estimator proposed in this paper is shown to be generally applicable in binary-choice models, robust to various kinds of contamination, and at the same time, asymptotically efficient under no contamination. The combination of these properties is not currently matched by any other existing robust method in the context of the binary-choice regression. Moreover, the proposed methods allows the use of a robust estimation procedure without sacrificing the quality of estimation, especially at larger samples.

Further improvements could be obtained by replacing the hard (complete) rejection of observations in MSTLE by weighting, which could then be determined in a data-adaptive way similar to the data-adaptive choice of trimming. Another interesting field of study is a combination of the adaptive MSTLE procedure with the MLE methods accounting for data misclassification (e.g., Hausman et al. 1998). Finally, the principle of the adaptive MSTLE estimation can be also applied to semi-parametric likelihood estimators (e.g., Klein and Spady 1993) under monotonicity constraint.
A. Assumptions

Further regularity assumptions used in Section 3.

Assumptions

4. The parameter space $B$ is compact.

5. The mixing coefficients $b_m$ of the sequence $\{x_i, y_i\}_{i \in \mathbb{N}}$ satisfy

$$m^{r/(r-2)}(\log m)^{2(r-1)/(r-2)}b_m \to 0$$

for $m \to \infty$ and some $r > 2$.

6. Expectation $E \sup_{\beta \in B} |l(x_i, y_i; \beta)|^r$ is finite.

7. Expectation $E \sup_{\beta \in U(\beta_0, \delta)} |l'(x_i, y_i; \beta)|^r$ is finite for some $\delta > 0$.

8. Expectation $E \sup_{\beta \in U(\beta_0, \delta)} |l''(x_i, y_i; \beta)|^{1+\varepsilon}$ is finite for some $\delta > 0$ and $\varepsilon > 0$.

B. Proofs

Proof of Lemma 1. Let us first derive an auxiliary results concerning function $h(t) = t \ln t + (1 - t) \ln(1 - t)$ for $t \in (0, 1)$. Taking its first derivative leads to $h'(t) = \ln t - \ln(1 - t)$, which is negative for $t < 1/2$ and positive for $t > 1/2$. Hence, $h(t)$ is decreasing for $t < 1/2$ and increasing for $t > 1/2$ (property P1).

Now, the conditional expectation to analyze can be rewritten as

$$E \left[ l(x_i, y_i; \beta_0) \right] r(x_i; \beta_0) \geq C$$

$$= E \left[ y_i \ln F(x_i^\top \beta_0) + (1 - y_i) \ln \{1 - F(x_i^\top \beta_0)\} \right] r(x_i; \beta_0) \geq C$$

$$= E \left[ E(y_i|x_i) \ln F(x_i^\top \beta_0) + (1 - E(y_i|x_i)) \ln \{1 - F(x_i^\top \beta_0)\} \right] r(x_i; \beta_0) \geq C$$
\[ E \left[ F(x_i^\top \beta_0) \ln F(x_i^\top \beta_0) + \{1 - F(x_i^\top \beta_0)\} \ln\{1 - F(x_i^\top \beta_0)\}\right] | r(x_i; \beta_0) \geq C. \]

Denoting random variable \( t = F(x_i^\top \beta_0) \), it follows that the trimming rule \( r(x_i; \beta_0) = \min\{\ln t, \ln(1 - t)\} \) and we can write

\[
E \left[ l(x_i, y_i; \beta_0) | r(x_i; \beta_0) \geq C\right] = E \left[ t \ln t + (1 - t) \ln(1 - t) | \min\{t, 1 - t\} \geq \exp(C)\right].
\]

Because condition \( \min\{t, 1 - t\} \geq \exp(C) \) means that \( t \in \langle \exp(C), 1 - \exp(C) \rangle \) for \( \exp(C) \leq 1/2 \) and increasing \( C \) shrinks this interval, property P1 implies that \( E \left[ t \ln t + (1 - t) \ln(1 - t) | \min\{t, 1 - t\} \geq \exp(C)\right] \) is non-increasing in \( C \). Hence, the result of the lemma follows from the fact that the order statistics \( r_{[n-h_n+1]}(x_i; \beta_0) \) decreases as \( h_n \) increases. □

**Proof of Theorem 1.** As discussed in Croux et al. (2002), an estimator of a binary-choice regression model can break down under contamination in two ways: either the estimates diverge and become infinite or they converge to a non-random zero vector. Assuming that the MLE estimate is identified, that is, there is an overlap in data, an estimator based on the likelihood criterion cannot diverge since some likelihood contributions would become infinite (see Croux et al. 2002, Theorem 1). Therefore, we only have to deal with the breakdown to a zero vector.

The adaptive MSTLE just chooses the amount of trimming \( \lambda \) on a grid \( 2/3 = \lambda_1 < \ldots < \lambda_M = 1 \). Hence, we only have to show that the adaptive procedure selects a MSTLE estimator that does not break down. Considering a sample of size \( n \) and the number of contaminated observations \( k \) such that \( k/n \leq \max_{m=1,\ldots,M} \epsilon_n^m \), there are sequences of samples with \( k \) additional (contaminated) observations such that the norm of the corresponding MSTLE estimate converges to 0 if \( k/n > \epsilon_n^m \)
and stays bounded away from 0 for any such sequence if \( k/n \leq \varepsilon_m; \ m = 1, \ldots, M \).

To verify the claim of the theorem, we thus have to show that the selection criterion at an MSTLE estimate \( \hat{\beta}^m \), which does not break down,

\[
S(h_n^m, \hat{\beta}^m) = \frac{1}{h_n^m} \sum_{j=1}^{n} l(x_i, y_i; \hat{\beta}^m) \cdot I\left(r(x_i; \hat{\beta}^m) \geq r_{n-h_n^m+1}(x_i; \hat{\beta}^m)\right), \tag{6}
\]

is larger than the selection criterion at \( \|\beta\| = 0. \)

To prove this, note that the selection criterion (6) is independent of \( h \) if \( \|\beta\| = 0 \) because \( l(x_i, y_i; 0) = \ln(1/2) \). If we now consider trimming \( h_n^m \) such that \( k/n \leq \varepsilon_m \), the corresponding MSTLE estimate \( \hat{\beta}^m \) does not break down and stays bounded away from 0. Since \( \hat{\beta}^m \) maximizes the trimmed likelihood (5), and thus, for a fixed \( h_n^m \), also the selection criterion (6), \( S(h_n^m, \hat{\beta}^m) > S(h_n^m, 0) = S(h, 0) \) for any \( h = [n/2], \ldots, n. \) \( \square \)

**Proof of Theorem 2.** The asymptotic normality of MSTLE directly follows from Čižek (2007, Theorem 3.3), where most distributional and functional assumptions of the theorem are parts of Assumptions 1–8. The exceptions are the identification assumptions, which are verified in Čižek (2007, Section 4.3) under Assumption 1–8, and assumptions that \( F_0 = \{r(x_i; \beta)|\beta \in B\} \) and \( F_1 = \{l'(x_i, y_i; \beta)|\beta \in U(\beta_0, \delta)\} \) form VC classes of functions, which are verified in the following paragraphs.

First, note that \( r(x_i; \beta) = \min\{\ln F(x_i^\top \beta), \ln[1 - F(x_i^\top \beta)]\} \). Since \( \{x_i^\top \beta|\beta \in B\} \) is (a part of) a finite dimensional vector space and \( \ln F \) is a monotonic function, \( F_0 \) is a VC class of functions (van der Waart and Wellner 1996, Lemmas 2.6.15 and 2.6.18).

Second, the derivative \( l'(x_i, y_i; \beta) \) of the likelihood contribution equals to

\[
l'(x_i, y_i; \beta) = \frac{y_i f(x_i^\top \beta)}{F(x_i^\top \beta)} - \frac{(1 - y_i) f(x_i^\top \beta)}{1 - F(x_i^\top \beta)}
\]
\begin{align*}
&= (2y_i - 1) \max \left\{ \frac{y_i f(x_i^\top \beta)}{F(x_i^\top \beta)}, \frac{(1 - y_i)f(x_i^\top \beta)}{1 - F(x_i^\top \beta)} \right\}, \\
\text{see (3). Because functions } f/F \text{ and } f/(1 - F) \text{ are derivatives of concave functions } \\
\ln F \text{ and } \ln(1 - F), \text{ respectively, they are monotonic. Hence, } F_1 \text{ is a VC class of functions by the same argument as above (van der Waart and Wellner 1996, Lemmas 2.6.15 and 2.6.18).} \quad \Box
\end{align*}

**Proof of Theorem 3.** The selection criterion determining the optimal amount of trimming can be expressed as

\[ C_m = \frac{1}{h_m} \sum_{j=1}^{n} l(x_i, y_i; \hat{\beta}^m) \cdot I\left( r(x_i; \hat{\beta}^m) \geq r_{[n-h_m+1]}(x_i; \hat{\beta}^m) \right). \quad (7) \]

By Theorem 2, the \( \hat{\beta}^m \rightarrow \beta_0 \) for all \( m = 1, \ldots, M \). This implies that the order statistics \( r_{[n-h_m+1]}(x_i; \hat{\beta}^m) \rightarrow R^{-1}(1 - \lambda_m) \) (Čížek 2007, Lemma A.2), where \( R \) denotes the distribution function of \( r(x_i; \beta_0) \). Note that, by Assumption 3, \( R \) is absolutely continuous, and by definition, \( R^{-1}(1 - \lambda_m) > R^{-1}(1 - \lambda_M) \) for \( m < M \) since \( \lambda_M = 1 \).

An immediate consequence is that, by Lemma 1 and Assumption 3, expectation

\[ E_m = E \left[ l(x_i, y_i; \beta_0) | r(x_i; \beta_0) \geq R^{-1}(1 - \lambda_m) \right] \]

as a function of \( m \) has a unique maximum at \( m = M \) (\( \lambda_M = 1 \)). Since Čížek (2007, Lemma A.1) implies that the average (7) converges to \( E_m \) uniformly in \( m \), one can find for any \( \varepsilon > 0 \) some \( n_0 \in \mathbb{N} \) such that \( |C_m - E_m| < (E_M - E_{M-1})/2 \) with probability higher than \( 1 - \varepsilon \), which implies \( P(m_n^* = M) \geq 1 - \varepsilon \) for any \( n > n_0 \). Thus, \( m_n^* \rightarrow M \) in probability, and consequently, \( \lambda_{m_n^*} \rightarrow 1 \) in probability as \( n \rightarrow \infty \).
Therefore,

\[
\sqrt{n}(\hat{\beta}^{(AMSTLE)} - \beta_0) = \sum_{m=1}^{M} \sqrt{n}(\hat{\beta}^{(MSTLE,\lambda_m n)} - \beta_0) I(m = m_n^*)
\]

\[
= \sqrt{n}(\hat{\beta}^{(MSTLE,n)} - \beta_0) + o_P(1)
\]

as \( n \to \infty \) by Theorem 2. This concludes the proof since \( \hat{\beta}^{(MSTLE,n)} = \hat{\beta}^{(MLE)} \). \( \Box \)
C. Further simulation results
