ABSTRACT

Broadening the stochastic assumptions on the error terms of regression models was prompted by the analysis of linear multivariate t models in Zellner (1976). We consider a possibly non-linear regression model under any multivariate elliptical data density, and examine Bayesian posterior and predictive results. The latter are shown to be robust with respect to the specific choice of a sampling density within this elliptical class. In particular, sufficient conditions for such model robustness are that we single out a precision factor $\tau^2$ that does not influence the way the density changes over ellipsoids, and that we specify an improper prior density on $\tau^2$. Apart from the posterior distribution of this nuisance parameter $\tau^2$, the entire analysis will then be completely unaffected by departures from Normality. Similar results hold in finite mixtures of such elliptical densities, which can be used to approximate more general data processes.

1. INTRODUCTION

The Bayesian analysis of regression models with dependent non-Normal error terms has received considerable attention, especially since the seminal paper of Zellner (1976), who considered linear multivariate Student $t$ regression models. This assumption was extended to scale mixtures of Normal distributions in Jamalama da et al. (1987) and in Chib et al. (1988) whereas Osiewalski (1990) and Chib et al. (1990) generalize, in addition, to nonlinear models. Here we shall examine a further generalization to the entire class of multivariate elliptical or ellipsoidal densities, as it was defined in e.g. Kelker (1970), Cambanis et al. (1981) or Dickey and Chen (1985).

In particular, we find that any multivariate elliptical regression model, combined with an improper reference prior on the "nuisance" scalar precision parameter $\tau^2$, will lead to exactly the same posterior and predictive analyses as in the Normal case. Thus, in this sense, our inference is fully robust with respect to changes in the specification of the sampling process within this wide class of elliptical densities. Remark that this property differs from robustness against extreme observations, as used e.g. in Ramsay and Novick (1980), who defined a concept of "$L$ robustness". The latter relates to the sensitivity of the likelihood to the data, and is based on the influence function. Instead, we arrive at robustness of posterior and predictive results with respect to the sampling model itself, within a broad class of models that includes many $L$ robust cases, like e.g. Student or Cauchy models. Thus, we focus on "model robustness" [see Berger (1985, p. 248)], and in particular, on what Box and Tiao (1973, p. 152) call "inference robustness".

These robustness results are derived for multivariate elliptical distributions, and do not generally hold under independent non-Normal error terms. If we assume that the errors are independently and identically distributed according to some elliptical process other than the Normal, no such robustness occurs. The results in Box and Tiao (1973, Ch. 3), West (1984) and Bagchi and Guttman (1988) provide some evidence in this respect. However, if we start from a multivariate elliptical framework, where independence can only be accommodated under Normality [see Kelker (1970, Lemma 5)], the usual improper reference prior on $\tau^2$ does the trick. Only posterior results for $\tau^2$ are affected by departures from Normality, as in Zellner (1976). Given the nuisance character of this scale factor, however, these results are not explicitly stated here. Predictive inference and posterior infer-
ence on the parameter $\theta$, which defines the location and shape of the ellipsoids, can then be conducted exactly as in the usual Normal case. The remaining parameter $\nu$ only serves to index the way the density function changes over ellipsoids, and the sample will only update the marginal prior on $\nu$ through its prior dependence on $\theta$.

A finite mixture of elliptical data densities is then considered for cases in which we want to avoid a symmetry assumption. The mixing will be preserved in posterior and predictive analyses, which allows broadening the class of data densities, without really affecting the complexity of the ensuing analysis. It is just like mixing Normal distributions defined over different ellipsoids, where the mixing parameter $\lambda$ will be revised by the sample, albeit in a rather moderate way.

Section 2 introduces the Bayesian model, on the basis of which we derive posterior and predictive results in Sections 3 and 4, respectively. The finite mixtures of data densities are examined in Section 5, whereas a final section summarizes some conclusions.

2. THE BAYESIAN MODEL

2.1. The Elliptical Sampling Model

A general form of elliptical, also known as ellipsoidal, distributions will be assumed for the sampling process. The observation vector $y$ has an $n$-variate continuous elliptical distribution, given a set of exogenous variables $X$ and a sufficient parameterization, say $\omega$, if and only if its data density is

$$
p(y | X, \omega) = |\tilde{V}(X, \eta)|^{-\frac{1}{2}} g_{n, \omega}
\left(\frac{(y - h(X, \beta))^\prime (\tilde{V}(X, \eta))^{-1} (y - h(X, \beta))}{\Gamma(n/2)}\right).
$$

(2.1)

In (2.1) $g_{n, \omega}(-)$ is a nonnegative function, which for any $n$ and $\omega$ has to fulfil the condition

$$
\int_0^\infty u^{\frac{n}{2} - 1} g_{n, \omega}(u)du = \Gamma\left(\frac{n}{2}\right). \tag{2.2}
$$

It can be shown [see Cambanis et al. (1981), Dickey and Chen (1985), Kelker (1970)] that (2.2) is both necessary and sufficient to make (2.1) a proper, normalized density function.

The location vector in (2.1) is the, possibly nonlinear, but known, function $h(X, \beta)$, and the scale matrix is $\tilde{V}(X, \eta)$, where $\tilde{V}$ is positive definite symmetric.
(PDS) and a known matrix function of $X$ and $\eta$. Therefore, $\beta \in B \subseteq \mathbb{R}^k$ and $\eta \in H \subseteq \mathbb{R}^t$ serve to define the isodensity ellipsoids of $y$. The labelling function $g_{n,\omega}$ that determines the density value for each of these ellipsoids [see e.g. Leamer (1978, p. 150)] is indexed by $n$ and $\omega$, which may contain parameters other than $\beta$ and $\eta$, introduced specifically for the purpose of describing $g_{n,\omega}$. Let us call these parameters $\nu \in N \subseteq \mathbb{R}^t$. A well-known example of this $\nu$ is found in the multivariate Student $t$ distribution, where $\nu \in \mathbb{R}^t$ and

$$g_{n,\omega}(\cdot) = g_{n,\nu}(\cdot) = \frac{\Gamma\left(\frac{n+\nu}{2}\right)}{\Gamma\left(\frac{n}{2}\right)} \left(\nu \pi\right)^{-\nu/2} (1 + \frac{\cdot}{\nu})^{-\frac{n+\nu}{2}}.$$ 

Indeed, from (2.1) we will then obtain a Student $t$ data density with $\nu$ degrees of freedom, location vector $h(X, \beta)$ and precision matrix $\tilde{V}(X, \eta)^{-1}$, denoted by

$$p(y \mid X, \omega) = f_\nu^2(y \mid \nu, h(X, \beta), \tilde{V}(X, \eta)^{-1}).$$

(2.3)

A generalization of (2.3), where the dimension of $\nu$ is extended, can be found in Dickey and Chen (1985, p. 173). However, in some cases none of the parameters in $\omega$ will appear in $g_{n,\omega}(\cdot)$, which will then only depend on $n$, the dimension of $y$. If, in particular, we choose

$$g_{n,\omega}(\cdot) = g_{n}(\cdot) = (2\pi)^{-\nu/2} \exp\left(-\frac{\nu}{2}\right),$$

our data density in (2.1) will be of the Normal form with mean $h(X, \beta)$ and covariance matrix $\tilde{V}(X, \eta)$:

$$p(y \mid X, \omega) = f_N^2(y \mid h(X, \beta), \tilde{V}(X, \eta)),$$

(2.4)

where $(\beta, \tilde{\eta})$ is now a sufficient parameterization. Neither of these well-known special cases correspond to an indexing of $g_{n,\omega}(\cdot)$ by the parameters appearing in the definition of the ellipsoid, namely $(\beta, \eta)$. Starting from the more restricted class of elliptical distributions that can be expressed as scale mixtures of Normals [see e.g. Kelker (1970)], such a dependence can easily be introduced through the density of the mixing parameter. Examples appeared in Osiewalski (1990), Osiewalski and Steel (1990) and Chib et al. (1990), who considered some specific densities of the general form

$$p(y \mid X, \omega) = \int_0^\infty f_n^2(y \mid h(X, \beta), \nu, \tilde{V}(X, \tilde{\eta})) \int_0^\infty \left(\frac{\nu + b_1(\beta, \tilde{\eta})}{2}, \frac{b_2(\beta, \tilde{\eta})}{2\nu}\right) dz$$

$$= f_n^2(y \mid \nu + b_1(\beta, \tilde{\eta}), h(X, \beta), \frac{\nu + b_1(\beta, \tilde{\eta})}{b_2(\beta, \tilde{\eta})}, \tilde{V}(X, \tilde{\eta})^{-1}),$$

(2.5)
where \( b_i(\beta, \eta), i = 1, 2, \) are positive functions of \((\beta, \eta)\) and \(f_G(\cdot | \cdot, \cdot)\) denotes a gamma density function. In the (more general) framework of (2.1), the density in (2.5) can be reproduced by choosing

\[
g_{n,\omega}(\cdot) = \frac{\Gamma\left(\frac{n + \nu + b_1(\beta, \eta)}{2}\right)}{\Gamma\left(\frac{\nu + b_1(\beta, \eta)}{2}\right) \pi^{\frac{n}{2}}} b_2(\beta, \eta)^{-\frac{n}{2}} \left(1 + \frac{\nu}{b_2(\beta, \eta)}\right)^{-\frac{n + \nu + b_1(\beta, \eta)}{2}},
\]

which clearly depends on \((\beta, \eta)\) as well.

The explanatory variables in \(X\) have a sampling distribution whose sufficient parameterization is denoted by \(\lambda\). If we assume the joint prior on \(\omega\) and \(\lambda\) is a product of \(p(\omega)\) and \(p(\lambda)\), both \(\sigma\)-finite, we can ignore the process of \(X\) for the purpose of conducting inference with (2.1). These assumptions, in fact, amount to operating a Bayesian cut [see e.g. Florens and Mouchart (1985) and Florens et al. (1990)].

We shall now introduce two restrictions on the class of models in (2.1), since this will open an avenue to drastic simplifications, using the property in (2.2), as will become clear in the sequel. Firstly, we restrict ourselves to those scale matrices \(V(X, \eta)\) that can be written as

\[
\tilde{V}(X, \eta) = \frac{1}{\tau^2} V(X, \eta),
\]

where \(\tau^2 \in \mathbb{R}_+\) is a scalar precision parameter, implicitly reparameterizing \(\eta\) as \((\tau^2, \eta)\). For notational convenience, we now define \(\theta = (\beta, \eta)\) which contains all the information about the location and shape of the ellipsoids.

Secondly, we shall assume that this scalar precision parameter \(\tau^2\) does not index the function \(g_{n,\omega}\), i.e.

\[
g_{n,\omega}(\cdot) = g_{n,\theta}(\cdot).
\]

This implies the interpretation for \(\tau^2\) can only be linked to the ellipsoids, and should, thus, be equivalent for all models in our class. Therefore, we can, at this level, before actually choosing a particular model, consider assigning a prior density to \(\tau^2\), as its meaning does not vary over the elliptical class in (2.1), restricted by (2.6) and (2.7).
Our framework now excludes densities like (2.5), unless the functions $b_1(\beta, \eta) = b_1(\beta, \tau^2, \eta)$ are constant in $\tau^2$, but cases where (2.7) is violated seem rather artificial and somewhat unlikely to occur in actual practice.

2.2. Prior Densities

We now face the task of completing the Bayesian model by assigning a prior distribution to $\omega = (\theta, \tau^2, \nu)$. Both $\theta$ and $\nu$ (if it appears) will typically be parameters of interest, and we shall leave the specification of their prior density completely free at this stage. We shall see in Section 3 that if we specify the ("usual") improper prior structure

$$p(\theta, \tau^2, \nu) = \frac{c}{\tau^2} p(\theta, \nu),$$

(2.8)

where $c$ is a positive constant and $p(\theta, \nu)$ is functionally independent of $\tau^2$, the analysis will simplify greatly. More in particular, provided $g_{n, \omega}(\cdot)$ is not indexed by $\tau^2$, its actual form becomes completely irrelevant, so that both posterior and predictive analyses are fully robust with respect to any departures from Normality in the wide class of remaining elliptical densities.

3. POSTERIOR INFERENCE

Combining the general class of elliptical data densities in (2.1), restricted only by (2.6) and (2.7), with the improper prior family in (2.8), we obtain the joint density

$$p(y, \omega | X) = c p(\theta, \nu) (\tau^2)^{3-1} | V(X, \eta) |^{-\frac{1}{2}} g_{n, \omega}[\tau^2 d(y, X, \theta)],$$

(3.1)

where we have defined

$$d(y, X, \theta) = (y - h(X, \beta))' V(X, \eta)^{-1} (y - h(X, \beta)).$$

Let us now consider the transformation from $(y, \theta, \tau^2, \nu)$ to $(y, \theta, r^2, \nu)$, where

$$r^2 = \tau^2 d(y, X, \theta),$$

(3.2)

leading to

$$p(y, \theta, r^2, \nu | X) = c p(\theta, \nu) | V(X, \eta) |^{-\frac{1}{2}} d(y, X, \theta)^{-\frac{3}{2}} (r^2)^{\frac{3}{2}-1} g_{n, \omega}(r^2).$$

(3.3)
The function $g_{\eta,\theta} (\cdot)$ is not affected by the transformation in (3.2), since it does not involve $r^2$, so that property (2.2) can directly be applied to integrate out $r^2$ in (3.3). This leaves us with

$$p(y, \theta, \nu | X) = c \Gamma \left( \frac{N}{2} \right) \pi^{-\frac{N}{2}} \int p(\theta, \nu) \left| V(X, \eta) \right|^{-\frac{1}{2}} d(y, X, \theta)^{-\frac{3}{2}}, \quad (3.4)$$

which no longer depends on the form of $g_{\eta,\theta} (\cdot)$. The joint (improper) density of our parameters of interest and $y$ is thus completely robust with respect to any departures from Normality in the class of elliptical data densities (2.1), restricted by (2.6) and (2.7), when $r^2$ is treated by assuming the improper prior (2.8).

Let us now assume that the prior $p(\theta, \nu)$ is integrable in $\nu$ over $N$, which makes (3.4) integrable in $\nu$, and also that the resulting density, $p(y, \theta | X) = \int_N p(y, \theta, \nu | X) d\nu$, is integrable in $\theta$ over $\Theta \subset B \times H$. We are then sure that the posterior of $(\theta, \nu)$ is well defined as

$$p(\theta, \nu | y, X) \propto p(\theta, \nu) \left| V(X, \eta) \right|^{-\frac{1}{2}} d(y, X, \theta)^{-\frac{3}{2}}, \quad (3.5)$$

from which we can easily derive the posterior for the location and shape parameters $\theta$.

**Theorem 1.** For any elliptical data density (2.1), fulfilling (2.6) and (2.7), and under an improper prior (2.8), which is integrable in $\nu$, we obtain the same posterior of $\theta$:

$$p(\theta | y, X) \propto p(\theta) \left| V(X, \eta) \right|^{-\frac{1}{2}} d(y, X, \theta)^{-\frac{3}{2}}, \quad (3.6)$$

where $p(\theta) = \int_N p(\theta, \nu) d\nu$ and we have assumed that (3.6) is integrable in $\theta$ over $\Theta$.

Of course, (3.6) is exactly the posterior one obtains for the Normal data density (2.4), and may look even more familiar if we consider the simple linear case:

**Corollary 1:** In the special linear case of Theorem 1 where $h(X, \beta) = X \beta$ and $\Theta = R^k \times H$, the posterior densities of $\theta$ are given by

$$p(\beta | \eta, y, X) = K(\eta)^{-1} p(\beta, \eta) f^*_\beta (\beta | n - k, \beta, s^{-2}X'V(X, \eta)^{-1}X) \quad (3.7)$$

and

$$p(\eta | y, X) \propto K(\eta) \left| V(X, \eta) \right|^{-\frac{1}{2}} \left| X'V(X, \eta)^{-1}X \right|^{-\frac{1}{2}} (s^2)^{-\frac{1}{2}(n-k)}, \quad (3.8)$$
where
\[
\hat{\beta} = (X'V(X, \eta)^{-1}X)^{-1}X'V(X, \eta)^{-1}y
\]
\[
s^2 = \frac{1}{n-k} (y - X\hat{\beta})' V(X, \eta)^{-1} (y - X\hat{\beta})
\]
and \(K(\eta)\), the inverse of the normalizing constant of (3.7), absorbs the prior information on \(\eta\).

Implicitly, we have also made the assumption that \(X\) is of full column rank in Corollary 1, which implies \(n \geq k\) in this linear case. If we specify a uniform prior on \(\beta\), i.e. \(p(\beta, \eta) \propto p(\eta)\), we simply have a Student t conditional posterior of \(\beta\), which is proper if \(n > k\). Moments of (3.7) then exist up to (not including) order \(n-k\). Adding some prior information will typically lead to the existence of higher order moments. In particular, if \(p(\beta, \eta)\) contains a Student t kernel for \(\beta\) with \(\nu_0\) degrees of freedom, the conditional posterior in (3.7) will be of a 2-0 poly-t form [see Drèze (1977) and Richard and Tompa (1980)], allowing for posterior moments up to order \(\nu_0 + n - k\).

The invariance results obtained here are a direct consequence of the fact that, after integrating out \(\tau^2\) under (2.8), we have
\[
p(y | X, \theta, \nu) = p(y | X, \theta) \propto d(y, X, \theta)^{-\frac{\nu}{2}},
\]
irrespective of the form of \(g_{n, \theta, \nu}(\cdot)\). Therefore, we address a particular case of Hill (1969), who proposed specifying a spherical model without considering a scale parameter. In the framework of (2.1) he does not impose (2.6) and introduces sphericity by assuming \(\tilde{V}(X, \tilde{\eta}) = I_n\) directly. The more "traditional" approach, in e.g. Zellner (1976), Jamjalamadaka et al. (1987), Chib et al. (1988) and Osiewalski (1990), implicitly starts from the deeper level of parameterization used here and amounts to assuming (2.6). In that case sphericity is induced by taking \(V(X, \eta) = I_n\). Hill's (1969) specification of general spherical errors is thus made at a level of parameterization comparable to the one in (3.9). By not imposing (2.6), Hill's approach is slightly more general, but at the cost of not obtaining the robustness that follows from (3.9). Nevertheless, Hill (1969) does introduce a scale factor in his discussion of Normality. At that level, our results imply that it is not the Normality assumption but the use of Jeffreys' prior on this scale factor [as in (2.8)] that accounts for finding the "usual" posterior results. Therefore, provided one is willing to accept (2.6), Normality does not seem to be quite as restrictive as suggested by Hill.
From the joint posterior of $\theta$ and $\nu$ in (3.5), it is already obvious that $\nu$ only appears through the joint prior $p(\theta, \nu)$. This means that given $\theta$ the sample contains no information regarding $\nu$, so that conditionally upon $\theta$ $\nu$ is not updated through the observations. Thus, under the conditions of Theorem 1, we always have that $p(\nu | \theta, y, X) = p(\nu | \theta)$, where the latter density is well defined since $p(\theta, \nu)$ is assumed to be integrable in $\nu$. The marginal prior on $\nu$, however, will generally be updated [see also Drèze and Richard (1983, p.522)], since it is given by the integral of (3.5) in $\theta$ over $\Theta$, which can be written as

$$p(\nu | y, X) \propto \int_{\Theta} p(\nu | \theta) p(\theta | y, X) d\theta$$

where $p(\theta | y, X)$ was defined in (3.6). Thus, if $p(\nu | \theta)$ does not depend on $\theta$ (i.e. independence in probability if $p(\theta)$ is proper and functional independence if it is not) the sample cannot revise the marginal prior of $\nu$ either and we state:

**Theorem 2:** Under the conditions of Theorem 1, the prior structure for $(\theta, \nu)$

$$p(\theta, \nu) = p(\theta) p(\nu)$$

will prevent updating of the marginal prior information on $\nu$, i.e.

$$p(\nu | y, X) = p(\nu).$$

The lack of dependence in (3.10), which is taken to be integrable in $\nu$, will, for any proper elliptical sampling model (2.1) fulfilling (2.6) and (2.7), lead to posterior independence of $\theta$ and $\nu$, provided we express our prior ignorance about $\tau^2$ by the class of improper densities in (2.8), and if the joint posterior exists, which is assured if (3.6) is integrable in $\theta$. This can be seen directly from (3.5), and, given the fact that the sample can only update $\nu$ through $\theta$, this posterior independence will make sure that our marginal opinions regarding $\nu$ will not be revised through the observations. Chib *et al.* (1990) analyse the particular subclass of (2.1) where the elliptical densities can be described as scale mixtures of Normals. A prominent member of this subclass is the Student $t$ model in (2.3), in which case Theorem 2 exactly reduces to their Corollary 4, stating a set of sufficient conditions for the impossibility to update the prior of the degrees-of-freedom parameter.
4. PREDICTIVE ANALYSIS

Alternatively, we can focus on the predictive properties of Bayesian models involving elliptical data densities as in (2.1) and improper priors as in (2.8), maintaining also (2.6) and (2.7).

For this purpose, we partition the $n$ dimensional vector $y$ as follows

$$y = \begin{pmatrix} y(1) \\ y(2) \end{pmatrix},$$

where $y(1) \in \mathbb{R}^{n_1}$ and $n_1 < n$, and we are interested in forecasting $y(2)$, given $y(1)$ and $X$. Conformably, we partition

$$h(X, \beta) = \begin{pmatrix} h(1)(X, \beta) \\ h(2)(X, \beta) \end{pmatrix} \equiv \begin{pmatrix} h(1) \\ h(2) \end{pmatrix},$$

and

$$V(X, \eta) = \begin{pmatrix} V_{11}(X, \eta) & V_{12}(X, \eta) \\ V_{21}(X, \eta) & V_{22}(X, \eta) \end{pmatrix} \equiv \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix},$$

where the defining equalities are just used to economize on notation. From (3.4) it is immediately clear that the form of $g_{n, \theta, \nu}(-)$ will not affect the predictive analysis either, and we obtain directly

$$p(y(1), y(2), \theta, \nu \mid X) = c \Gamma\left(\frac{n_1}{2}\right) \pi^{-\frac{n_1}{2}} p(\theta, \nu) \mid V_{11} \mid^{-\frac{1}{2}} a(y(1), X, \theta)^{-\frac{n_1}{2}},$$

$$f_S^{n_2}(y(2) \mid n_1, h(2) + V_{21}V_{11}^{-1}(y(1) - h(1)), \frac{n_1}{a(y(1), X, \theta)} V_{22}^{-1}),$$

(4.1)

with $a(y(1), X, \theta) = (y(1) - h(1))^t V_{11}^{-1} (y(1) - h(1))$ and $V_{22.1} = V_{22} - V_{21}V_{11}^{-1}V_{12}$. Given our assumption of integrability of the joint prior in $\nu$, it is trivial to integrate it out, as in Section 3. The posterior of $\theta$ given the first subsample $y(1)$ will be of exactly the same form as (3.6) in Theorem 1, but with $y(1)$ instead of $y$ throughout:

$$p(\theta \mid y(1), X) \propto p(\theta) \mid V_{11} \mid^{-\frac{1}{2}} a(y(1), X, \theta)^{-\frac{n_1}{2}},$$

(4.2)

provided (4.2) is integrable in $\theta$ over $\Theta$. The predictive density thus becomes the Student density in (4.1) of $y(2)$, given $y(1)$, $X$ and $\theta$, weighted by this posterior on the basis of $y(1)$:

$$p(y(2) \mid y(1), X) = \int_\Theta p(y(2) \mid y(1), X, \theta) p(\theta \mid y(1), X) \, d\theta.$$

(4.3)
As was to be expected from (3.4), the general elliptical character of the data density does not induce any difference in our predictive analysis with respect to the Normal framework. Remark that integrating out $r_z$ in (3.3), under the prior (2.8), always leads to a density of $y$, given $\theta$ and $X$, proportional to $d(y, X, \theta)^{-\frac{1}{2}}$, as was stressed in Section 3. This, of course, implies the Student density of $y(2)_z$, given $y(1), \theta$ and $X$, but this Student $t$ form will generally be lost when we integrate out $\theta$ in the predictive density as in (4.3).

A predictive analysis on the basis of (4.3) can be called for when e.g. the observations on $y(2)$ are missing, whereas both $y(1)$ and the entire $X$ matrix are observed. However, in actual practice, it is often the case that only a submatrix of $X$, say $X_1$, is jointly observed with $y(1)$, so that the posterior information available for forecasting is only based on $y(1)$ and $X_1$. We then set out to predict $y(2)$, given the observed $(y(1), X_1)$ and a set of exogenously given values for the remaining part of $X$, say $X_2$. Given our maintained assumption of independence between $X$ and $\omega$, it is sufficient to assume

$$h(1) = h(1)(X_1, \beta) \quad \text{and} \quad V_{11} = V_{11}(X_1, \eta)$$  \hspace{1cm} (4.4)

in order to have posterior independence between $\theta$ and $X_2$.

**Theorem 3:** Under the conditions of Theorem 1 and (4.4) any elliptical sampling model (2.1) will allow conditional forecasting based on the predictive density

$$p(y(2) \mid y(1), X) = \int_{\Theta} f_{\beta}^{n_1}(y(2) \mid n_1, h(2) + V_{21}V_{11}^{-1}(y(1) - h(1)), \theta)\, \frac{n_1}{a(y(1), X_1, \theta)}\, V_{22}^{-\frac{1}{2}} \, p(\theta \mid y(1), X_1) \, d\theta,$$  \hspace{1cm} (4.5)

and $p(\theta \mid y(1), X_1)$ is obtained from (4.2) but now with (4.4) holding.

The improper prior on $\tau^2$ in (2.8), conditions (2.6)-(2.7) and the existence of the posterior thus lead to perfect predictive robustness which can be used in current practice under assumption (4.4).

In the simplest linear case with a uniform prior on $\theta = \beta$, we can write:

**Corollary 2:** If $h(X, \beta) = X\beta$, $V(X, \eta) = V$ is assumed known and $\Theta = IR^k$, then under a uniform prior on $\theta = \beta$ the predictive (4.5) in Theorem 3 reduces to the Student density

$$p(y(2) \mid y(1), X) = f_{\beta}^{n_1}(y(2) \mid n_1 - k, X_2\hat{\beta}_1 + V_{21}V_{11}^{-1}(y(1) - X_1\hat{\beta}_1), s_{\theta}^{-2}W^{-1})$$  \hspace{1cm} (4.6)
A uniform prior of $\beta$ has to be used for obtaining the Student predictive in (4.6), since we have left the class of prior densities that are natural conjugate for the Normal case (2.4) by assuming prior (functional) independence between $\beta$ and $\tau^2$ in (2.8).

5. FINITE MIXTURES OF ELLIPTICAL DATA DENSITIES

Although the class of sampling models described in (2.1), and restricted only by (2.6)-(2.7), can already cover many cases used in practical applications, it is still constrained to symmetry and, provided $g_{\eta^2}(\cdot)$ is strictly monotonic, to unimodality. If we wish to circumvent these restrictions, e.g. when faced with a blatantly skewed multimodal empirical data characterization, we can consider the use of finite mixtures of data densities as in (2.1), with (2.6) and (2.7) holding.

Finite mixtures of conjugate prior densities were used to approximate more general classes of priors in Dalal and Hall (1983) and Diaconis and Ylvisaker (1985), but here we introduce the mixing in the sampling model instead. This, of course, widens the family of data densities we can accommodate, and, in principle, $p(\theta, \nu)$ can also involve prior mixtures in our framework, although the latter point will not be elaborated here. We feel it is important to allow for a large enough class of sampling models, since the likelihood is (too) often felt to have some “external validity” [see Berger (1985, p. 249)], and therefore not questioned, whereas we “agree to disagree” on the formulation of the prior. In the terminology of Poirier (1988, p. 130) the “window” entertained should be large enough to interest a “sizeable audience of like-minded researchers”. Assessment methods for finite mixtures are found in Dickey and Chen (1985, Section 5), based on elicited quantiles.

If we suitably extend $\theta = (\beta, \eta)$ and $\nu$ to parameterize a finite number of densities as in (2.1), each of which has the same scalar precision parameter $\tau^2$, with

$$
\hat{\beta}_1 = (X_1'V_{11}^{-1}X_1)^{-1}X_1'V_{11}^{-1}y(1)
$$

$$
s_1^2 = \frac{1}{n_1 - k} (y(1) - X_1\hat{\beta}_1)' V_{11}^{-1}(y(1) - X_1\hat{\beta}_1)
$$

$$
W = (X_2 - V_21V_{11}^{-1}X_1)(X_1'V_{11}^{-1}X_1)^{-1} (X_2 - V_21V_{11}^{-1}X_1)' + V_{22.1}
$$

and $V_{22.1}$ defined as in (4.1).
we still have to introduce a mixing parameter $\lambda$. Let us, more in detail, analyse the case where we mix only two elliptical densities, implying that $\lambda$ is scalar. The relevant sampling model becomes

$$p(y \mid X, \omega, \lambda) = \lambda \frac{1}{\tau^2} V(X, \eta)[(y - h(X, \beta))' \left( \frac{1}{\tau^2} V(X, \eta) \right)^{-1}(y - h(X, \beta))]$$

$$+ (1 - \lambda) \frac{1}{\tau^2} W(X, \eta)[(y - m(X, \beta))' \left( \frac{1}{\tau^2} W(X, \eta) \right)^{-1}(y - m(X, \beta))],$$

$$0 \leq \lambda \leq 1. \quad (5.1)$$

were both $g_{n,\omega}(\cdot)$ and $k_{n,\omega}(\cdot)$ satisfy condition (2.2), and $m(\cdot)$ and $W(\cdot)$ are known functions in $\mathbb{R}^n$ and the space of all $n \times n$ PDS matrices, respectively. The nuisance parameter $\tau^2$ does not index either of the functions $g_{n,\omega}(\cdot)$ and $k_{n,\omega}(\cdot)$, and we assume the improper prior structure, integrable in $\nu$ over $N$:

$$p(\omega, \lambda) = \frac{c}{\tau^2} p(\theta, \nu, \lambda). \quad (5.2)$$

As in Section 3, this will result in a joint density of $(y, \theta, \nu, \lambda \mid X)$ that no longer involves the functions $g_{n,\omega}(\cdot)$ or $k_{n,\omega}(\cdot)$. Under the prior in (5.2), mixing any elliptical data densities with common $\tau^2$ has the same consequences for both posterior [on $(\theta, \lambda)$] and predictive inference as the mixing of Normals. In particular, if the joint density of $(y, \theta, \lambda \mid X)$ is integrable in $(\theta, \lambda)$, the posterior of $(\theta, \lambda)$ will be

$$p(\theta, \lambda \mid y, X) \propto p(\theta, \lambda) \{ \lambda \mid V(X, \eta)[(y - h(X, \beta))' \left( \frac{1}{\tau^2} V(X, \eta) \right)^{-1}(y - h(X, \beta))]$$

$$+ (1 - \lambda) \frac{1}{\tau^2} W(X, \eta)[(y - m(X, \beta))' \left( \frac{1}{\tau^2} W(X, \eta) \right)^{-1}(y - m(X, \beta))],$$

$$d(y, X, \theta) = d(y - m(X, \beta))' W(X, \eta)^{-1}(y - m(X, \beta)), \quad (5.3)$$

with $d(y, X, \theta)$ as in (3.1) and $p(\theta, \lambda) = p(\theta, \nu) W(X, \eta)^{-1}(y - m(X, \beta))$, whereas the prior density

$$p(\theta, \lambda) = \int_N p(\theta, \nu, \lambda) d\nu$$

must be at least integrable in those elements of $\theta$ that appear in only one of the mixed densities in (5.1), due to the summation character of mixtures. The posterior density in (5.3) is a generalization of (3.6), which it reduces to for $\lambda = 1$. For nondegenerate $\lambda$, however, the mixing in the data density (5.1) is carried over to the posterior. A convenient choice for the prior of $\lambda$ may be a beta density, independent of $\theta$, i.e.

$$p(\theta, \lambda) = p(\theta) f_B(\lambda \mid p, q) \quad (5.4)$$

with $0 \leq \lambda \leq 1$ and $p, q > 0$. 

From (5.3) we then obtain the conditional posterior of $\lambda$ as a mixture of beta densities
\[ p(\theta \mid y, X) = (p a_\theta + q b_\theta)^{-1} \left[ p a_\theta f_B(\lambda \mid p + 1, q) + q b_\theta f_B(\lambda \mid p, q + 1) \right], \quad (5.5) \]
where we have defined
\[ a_\theta = \int V(X, \eta) \left| \frac{1}{2} d(y, X, \theta)^{-\frac{1}{2}} \right. \]
\[ b_\theta = \int W(X, \eta) \left| \frac{1}{2} e(y, X, \theta)^{-\frac{1}{2}} \right. \]

It is interesting to note that the prior mean of $\lambda$, given by $E(\lambda) = \frac{p}{p+q}$, is revised by the data evidence according to the relative posterior “fits” of the elliptical densities in the mixture. If the density multiplied by $\lambda$ in (5.1) fits badly relative to the other one, $a_\theta$ will be much smaller than $b_\theta$; in the extreme case that $a_\theta = 0$, we obtain
\[ E(\lambda \mid \theta, y, X) = E(\lambda \mid y, X) = \frac{p}{p+q+1}, \]
a downward revision of the mean by the sample information. The other extreme with $b_\theta = 0$ will lead to
\[ E(\lambda \mid \theta, y, X) = E(\lambda \mid y, X) = \frac{p+1}{p+q+1}, \]
which is larger than the prior mean. So, although the conditional posterior mean of $\lambda$ generally depends on $\theta$, the marginal mean will always be confined to the region $[\frac{p}{p+q+1}, \frac{p+1}{p+q+1}]$. Under a uniform prior for $\lambda$ ($p = q = 1$), the posterior mean will be in $[\frac{1}{3}, \frac{2}{3}]$, an interval which will shrink very quickly if moderately strong prior information on $\lambda$ is introduced. In the case that we choose $E(\lambda) = \frac{1}{2}$ (i.e. $p = q$) the length of this interval is only four times the prior variance of $\lambda$. It thus seems the data evidence can only mildly influence our opinions concerning $\lambda$.

The marginal posterior density of $\theta$ will be given by
\[ p(\theta \mid y, X) \propto p(\theta) (p a_\theta + q b_\theta), \]
which can be written as the following mixture of the “individual” posteriors, each calculated as in (3.6) on the basis of one of the elliptical models in (5.1):
\[ p(\theta \mid y, X) = (pK_\theta + qK_\theta)^{-1} \left[ pK_\theta p_\theta(\theta \mid y, X) + qK_\theta p_\theta(\theta \mid y, X) \right], \quad (5.6) \]
where
\[ p_a(\theta \mid y, X) = K_a^{-1} p(\theta) a_\theta \]
\[ p_b(\theta \mid y, X) = K_b^{-1} p(\theta) b_\theta. \]

This formulation clearly puts into focus the role of the normalizing constants \( K_a \) and \( K_b \), which contribute to the “weights” in the same way as \( p \) and \( q \). A similar function was performed by \( a_\theta \) and \( b_\theta \) in (5.5). Of course, (5.6) reduces to (3.6) for \( q = 0 \), in which case (5.4) groups all the prior mass at the point \( \lambda = 1 \).

From the posterior density in (5.3) it becomes apparent that, unless the functional forms of \( h(\cdot) \) and \( m(\cdot) \) or those of \( V(\cdot) \) and \( W(\cdot) \) differ, the mixing in (5.1) will not affect the inference at all. Indeed, then the posterior of \( \lambda \) in (5.5) will reduce to the beta density in the prior (5.4), and the posterior of \( \theta \) will be the same as (3.6) in Section 3.

Let us now generalize the main results of this section to mixtures of \( \ell > 2 \) proper elliptical densities. We shall retain the improper prior as in (5.2) for the common nuisance parameter \( r^2 \), but \( \lambda \) will now be of dimension \( \ell \), and we shall, therefore, generalize the beta prior in (5.4) to a Dirichlet prior on \( \lambda \), with the parameter vector \( \alpha = (\alpha_1 \ldots \alpha_\ell)' \), \( \alpha_i > 0 \), \( \forall \, i \):
\[ p(\lambda \mid \theta) = p(\lambda) = f_D^\ell(\lambda \mid \alpha), \]
where \( \lambda \) is restrained to the unit simplex (i.e. \( \lambda_i > 0 \), \( \forall \, i \) and \( \sum_{i=1}^\ell \lambda_i = 1 \)). Analogously to \( a_\theta \) and \( b_\theta \) in the case \( \ell = 2 \), we define \( c_\theta^i \) for the \( i \)th density in the mixture, and we denote by \( e^i \) the \( \ell \)-dimensional vector with one in the \( i \)th position and zeros elsewhere. Then we can state:

**Theorem 4:** Finite mixtures of \( \ell \) elliptical densities, i.e. an obvious extension of (5.1), with common nuisance parameter \( r^2 \) on which the improper prior (5.2) is defined, will, under (5.7), lead to
\[ p(\theta \mid y, X) = \left( \sum_{i=1}^\ell \alpha_i c_\theta^i \right)^{-1} \left[ \sum_{i=1}^\ell \alpha_i c_\theta^i f_D^\ell(\lambda \mid \alpha + e^i) \right] \]
\[ p(\theta \mid y, X) = \left( \sum_{i=1}^\ell \alpha_i K_i \right)^{-1} \left[ \sum_{i=1}^\ell \alpha_i K_i p_i(\theta \mid y, X) \right], \]
where \( p_i(\theta \mid y, X) = K_i^{-1} p(\theta) c_\theta^i, \forall \, i \), provided all these posterior densities are well defined.
Since the posterior results in (5.8) and (5.9) are also finite mixtures, their analysis is not more difficult than with a single elliptical sampling density. Just like in the previous section, prediction can also be based on mixed sampling models, now using the posterior densities for both $\lambda$ and $\theta$. Again, we end up with a mixture, as formally stated in the final theorem.

**Theorem 5:** Under the conditions of Theorem 4, we can base our predictions for a finitely mixed elliptical model on the predictive density

$$p(y(2) \mid y(1), X) = \left( \sum_{i=1}^{t} \alpha_i L_i \right)^{-1} \left[ \sum_{i=1}^{t} \alpha_i L_i \ p_i(y(2) \mid y(1), X) \right], \quad (5.10)$$

which is itself a mixture of

$$p_i(y(2) \mid y(1), X) = \int_{\Theta} p_i(y(2) \mid y(1), X, \theta) \ p(\theta \mid y(1), X) \ d\theta,$$

where $p_i(y(2) \mid y(1), X, \theta)$ is the Student $t$ density in (4.1) now corresponding to the $i$th data density in the mixture, and

$$p_i(\theta \mid y(1), X) = L_i^{-1} \ p(\theta) \ |V_i| \ ^{-\frac{1}{2}} \ a_i(y(1), X, \theta)^{-\frac{\nu}{2}},$$

as in (4.2), where each $L_i$ must be finite, and indices $i$ refer to the $i$th data density throughout.

As in Section 4, if we wish to use posterior densities for $\theta$, computed after observing $y(1)$ and only part of $X$, namely $X_1$, we need a bit more. Imposing condition (4.4) on every data density that is used in the sampling model will be sufficient.

We suggest approximating non-elliptical (e.g. asymmetric) sampling processes by such finite mixtures of elliptical densities, since the mixing will be preserved in both posterior and predictive analyses. We thus have a way of considerably broadening the class of data densities, without really adding to the complexity of the analysis.
6. CONCLUDING REMARKS

Under certain conditions, it was shown that Bayesian posterior and predictive analysis is perfectly robust with respect to the choice of a sampling density within the entire class of elliptical densities. Sufficient conditions are that we can single out a scale factor \( \tau^2 \) that does not influence the way the density changes over ellipsoids, and that we specify an improper prior density on \( \tau^2 \).

Once the scale factor is then integrated out, the tails of the sampling density do not matter anymore, only the location and shape of the ellipsoids, parameterized by \( \theta \), are relevant. The posterior of \( \theta \) will then be given by the simple expression in Theorem 1, which is the same as in the Normal case. The only purpose of the parameter \( \nu \) is to describe the tails of the data density. Thus, if the latter become irrelevant, then, clearly, the sample can not directly revise our opinion about \( \nu \). It can only do so through revising \( \theta \) if there is prior dependence between \( \theta \) and \( \nu \). This is the object of Theorem 2.

Our conclusions are similar for prediction: given an improper prior on the nuisance parameter \( \tau^2 \), everything is just like in the Normal regression model. Theorem 3 summarizes these findings.

The results from Sections 1 through 4 can be related to previous work in this area; in particular, our paper extends the framework of scale mixtures of Normal densities, found in Jammalamadaka et al. (1987), Chib et al. (1988), Osiewalski (1990) and Chib et al. (1990), to general elliptical densities. It also broadens the linear regression model, used in the first two of the above references, to a possibly nonlinear one. Taking into account that only a diffuse prior for \( \tau^2 \) was considered in the present paper, we can establish the following correspondences. Within the class of scale mixtures of Normals, Proposition 1 of Jammalamadaka et al. (1987) is a special case of our Corollary 2 for \( V(X, \eta) = I_n \), whereas Theorem 3 generalizes Proposition 1 of Chib et al. (1988), who assumed linearity and a uniform prior on \( \beta \). Both Theorems 1 and 3 extend results obtained under scale mixtures of Normals in Osiewalski (1990) to general elliptical densities, and Theorem 2 generalizes Theorem 2 in Chib et al. (1990) in the same way.

If the inherent symmetry of the single elliptical data density is found to be too restrictive, we can make use of finite mixtures of elliptical densities to approximate some non-elliptical data density. These mixtures are then carried over to posterior
and predictive results, without leading to an increase in complexity (see Theorems 4 and 5, respectively). Since we have updating of the mixing parameter $\lambda$ as well, we could even think of incorporating this into a testing framework, where we intend to choose between several competing models. The updating of the prior of $\lambda$ by the sample will indicate which model is most favoured on the grounds of posterior fit. Note that the contenders have to correspond to different ellipsoids, e.g. through different functional form or choice of regressors. Mixing e.g. a Normal and a Cauchy defined over the same ellipsoid will, of course, give the same results as with a single Normal data density. Also, we have seen that the sample information on $\lambda$ can easily be drowned by moderately informative prior notions.

The findings in this paper generalize and explain many results that have appeared in the literature, and give remarkably weak sufficient conditions for robustness with respect to the data density. This provides us with a fairly strong argument in favour of using the standard Normal results in regression models, and gives an implicit motivation for stressing sensitivity with respect to the choice of the prior density instead.
