Negative association of concomitant physical symptoms with the course of major depressive disorder: A systematic review

Klaas M.L. Huijbregts,⁎ Christina M. van der Feltz-Cornelis, Harm W.J. van Marwijk, Fransina J. de Jong, Daniëlle A.W.M. van der Wind, Aartjan T.F. Beekman

Objective: The prognosis of depression greatly varies among patients, and the physical symptoms that often accompany depression may predict treatment resistance and a worse outcome. If so, this may have important clinical implications. The aim of this systematic review was to explore the association of concomitant physical symptoms with the outcome of major depressive disorder (MDD).

Methods: Systematic review: Medline, Psychinfo, and the Cochrane Library were searched for prospective, cross-sectional, and retrospective studies, and also for open-label trials and randomized controlled trials. The risk of bias assessment and data extraction were performed in duplicate. A qualitative best-evidence synthesis was performed, based on the number of studies reporting on the association between physical symptoms and the course of MDD, the consistency of the results, and the methodological quality. The findings were reported according to the PRISMA guidelines.

Results: Nine studies met the inclusion criteria. Although the design, outcome measures, and data presentation varied too much to make statistical pooling possible, the best evidence synthesis resulted in strong, consistent evidence for a negative association between physical symptoms and the course of MDD.

Conclusion: This systematic review shows a negative association of concomitant physical symptoms with the course of MDD. The effect might be considerable, but the number of studies addressing this topic is small and there was a wide variation in the study designs and outcome measures. More research is needed.

Keywords: Depression; Comorbidity; Effect modifiers (epidemiology); Somatisation; Systematic review; Physical symptoms

Introduction

The Global Burden of Disease Study, carried out by the WHO, reports that major depressive disorder (MDD) is expected to be the second leading cause of disability-adjusted life-years in 2020 [1]. Both psychological and pharmacological interventions are effective in the treatment of MDD, but like in other fields of medicine, efficacy trials where it is possible to control certain conditions, do not always produce the same results as effectiveness trials in real world settings [2]. Results from the STAR*D study, for instance, show that remission rates in response to treatment with a selective serotonin reuptake inhibitor (SSRI) are as low as 26.6% in primary care [3]. These rates improve after subsequent treatment steps, but remission is not easily achieved [4]. This might lead to unnecessary suffering and high costs for society [5,6].

MDD may be difficult to treat in everyday practice, as a result of concomitant physical symptoms interfering with...
the course, or because depressed patients who experience many physical symptoms may be less motivated to undergo treatment. This is an important subject for study, in view of the frequent co-occurrence of physical symptoms and MDD. Studies in primary care, for instance, have found that up to 70% of MDD patients only report physical symptoms when first presenting to a general practitioner [7]. Moreover, a recent study [8] reported that it is 4.43 times more likely for a depressed patients to have a somatiform disorder than for patient who is not depressed (confidence interval: 2.73–7.19).

Examples of symptoms that often co-occur with MDD are pain, fatigue, disturbed sleep, indigestion, dizziness, and fainting [9,10]. The more of these symptoms a patient experiences, the greater the probability that he or she is also suffering from a depressive disorder [9,10]. The importance of physical symptoms in patients suffering from MDD will also be recognized by clinicians, many of whom find patients with physical comorbidity difficult to treat. A recent systematic review provided evidence that pain predicts a longer time to remission in patients suffering from MDD [11].

To our knowledge, evidence with regard to the prognostic effect of the wider spectrum of concomitant physical symptoms—not restricted to pain—on the course of MDD has not yet been reviewed. Identifying factors that may predict treatment resistance or poor outcome are important, both for the education of patients and the selection of appropriate treatment. We therefore conducted a systematic review of studies that assessed the associations between physical symptoms and the prognosis of MDD. The association in terms of prognostic value in cohort studies, as well as the modification of treatment effect in trials can provide valuable information about this topic. Both types of studies were therefore included.

Method

Information sources and eligibility criteria

The search was performed in Medline, Psychinfo, and the database of the Cochrane Collaboration. The search focused on retrospective and prospective designs, as well as on open-label trials and randomized controlled trials. Studies had to meet the following criteria in order to be included:

1. At baseline, an assessment had to be made to determine whether patients were suffering from MDD. There was no restriction as to how MDD was diagnosed. At follow-up, an assessment had to be made about the outcome of the disorder. This could include clinical outcomes such as symptom reduction on a scale measuring depressive symptoms, response in terms of a decrease of a certain percentage on a scale measuring depressive symptoms, and time to such a response.

2. An assessment of physical symptoms had to be included at baseline. Since this review focused on a wider spectrum of physical symptoms than just one individual symptom, such as pain, special attention was paid to the way in which these symptoms were identified. The assessment of physical symptoms at baseline could not be limited to just one symptom. Furthermore, the studies had to include either:
   (a) a validated (sub-)scale to measure physical symptoms
   (b) information about physical symptoms from medical records
   (c) an assessment of physical symptoms by a medical practitioner.

With regard to the sub-criterion (a) (validated measures), we decided that the anxiety/somatization sub-scale of the Hamilton Depression Inventory 17-item version (HAMD-17) [12] could not be used as a valid measure of physical symptoms for the purpose of our review. This sub-scale consists of six items that reflect on both psychological and somatic symptoms of depression and anxiety. Therefore, studies had to use some other instrument to assess physical symptoms.

3. Studies had to report sufficient information on the association between physical symptoms and the outcome or course of MDD, expressed as odds ratios (OR), relative risks (RR), beta-coefficients (β), hazard ratios (HR), effect sizes, or mean differences.

Search

The exact keywords and Mesh-terms are available upon request. Briefly, we combined multiple keywords and medical subject headings (Mesh-terms) for MDD with multiple keywords regarding information on the outcome or course of the disorder and keywords referring to the design of the study. Finally, 102 symptoms and symptom-related keywords were added to the search, ranging from pain and fatigue to somatoform disorders or somatization, and including symptoms such as headache, nausea, and gas. Our search strategy is described in more detail in the Appendix.

The following searches were conducted:

- Medline was searched from its onset to November 24, 2008. There was no restriction as to the publication date of a study. The searches in Medline were periodically updated after the 24th of November 2008, but no additional papers were identified before submission of this document. There was no language restriction included in the search.
- Psychinfo was searched until March 25, 2009. Again, there was no restriction with regard to publication date or language.
The Cochrane Library database was searched until March 25, 2009. Again, there was no restriction with regard to publication date or language.

### Study selection, risk of bias assessment, and data collection process

All titles and abstracts \((N=2327)\) were read by one of the authors (K.H.). Full-text publications of studies that were potentially eligible for inclusion \((N=82)\) were read by two reviewers (K.H. and C.F.C.). They both checked the criteria for eligibility. Consensus was reached in all cases. In this stage, the quality of the papers was not assessed. Nine papers met the eligibility criteria. These were included in the review and were submitted to full quality assessment, performed independently by two assessors (K.H. and C.F.C.) who were unaware of each other’s assessments. The studies were assessed according to a list of predefined criteria described in a systematic review [13]. This checklist is based on previously used validity checklists [14], theoretical considerations, and methodological aspects of prognostic research [15,16]. Any disagreements among the reviewers were resolved by asking a third independent assessor (HvM) to assess the study on the criterion that caused disagreement. In all cases consensus was reached. The list of criteria is described in the first column of Table 2. A study was considered to be of high quality if 60% or more of the quality criteria were met (10 or more criteria out of 16).

Data were extracted on changes in the severity of depressive symptoms and the association of this outcome with physical symptoms. The type of association varied among the studies and could be presented as ORs, regression coefficients, correlation coefficients, or mean changes. Data were also extracted on the design of the study, the setting, the characteristics of the study population, the treatment of depression, and the duration of the follow-up.

Data-extraction was performed independently, and in duplicate, by two members of the research group (K.H. and C.F.C.).

### Synthesis of results

The methods used to describe the outcome of MDD and the methods used to present the association with physical symptoms were not operationalized in a satisfactory way (HAMD17 or only pain or fatigue and no focus on other symptoms).

symptoms varied widely in the studies that were included in this review. Outcome was presented as: time to a clinically relevant response to treatment, probability of a clinically relevant response, or mean change on a scale measuring depressive symptoms. Also presented were the association between physical symptoms and adherence to pharmacotherapy, or adverse effects of the treatment.

The outcome measures essentially reflected two types of association between physical symptoms and MDD: they either described the association between physical symptoms and the outcome of MDD (Type A) or they described the association between physical symptoms and adherence to pharmacotherapy for MDD (Type B). These two types of associations were analyzed separately.

The way in which the studies operationally defined association varied considerably. This variation in outcome assessment and data-presentation precluded an overall meta-analysis because this would not provide meaningful estimates of effect for one clinically relevant outcome measure. Therefore, we performed a qualitative analysis and presented a best-evidence synthesis. The number of studies reporting on the association between physical symptoms and the course of MDD, the consistency of the results, and the methodological quality were taken into account. A priori, findings were considered to be consistent if 75% or more of the studies reporting on a factor showed the same direction of the association. A study was considered to be of high quality if it met 60% or more of the quality criteria described in the first column of Table 2.

The definition of a level of evidence for the direction of association was based on earlier methods used to summarize the findings of observational research [13,17,18]. The level of evidence could have one of the following values:

- **Strong**: consistent and statistically significant associations in at least two high-quality cohorts.
- **Moderate**: consistent and statistically significant association in one high-quality cohort and at least one low-quality cohort.
- **Weak**: statistically significant association in one high-quality cohort or consistent and statistically significant in at least three low-quality cohorts.
- **Inconclusive**: association in less than three low-quality cohorts, regardless of statistical significance.
- **Inconsistent**: inconsistent findings, irrespective of study quality.
- **Insufficient**: only one study presenting non-statistically significant association, irrespective of quality.

## Results

### Study selection and characteristics

The searches in Medline, Psychinfo, and the Cochrane Library yielded 2377 hits. All of the abstracts were written in English. A total of 1718 articles were excluded because they were not published in English or because the description of the study was not available. The remaining 659 articles were then screened by title and abstract. A total of 462 articles were considered irrelevant and were therefore excluded. The reasons for exclusion were mainly related to the type of intervention, the population studied, or the research question addressed. A total of 197 articles were then selected for full-text review.

A total of 13 articles were excluded because they did not meet the inclusion criteria. The remaining 184 articles were then analyzed in detail. A total of 157 articles were excluded because they did not meet the inclusion criteria. The reasons for exclusion were mainly related to the type of intervention, the population studied, or the research question addressed. A total of 27 articles were then selected for final analysis.

a language that could be interpreted by the authors. Nine studies met the inclusion criteria.

The results of the searches are shown in a flowchart (Fig. 1) that was designed according to the PRISMA guidelines [19].

The characteristics of the studies that were included are presented in Table 1.

### Risk of bias

The results of the risk of bias assessment are presented in Table 2.

Initial agreement between the assessors was reached in 69% of all cases. All differences in opinion were solved by discussion, and consensus was reached in all cases.

The mean quality score was 66%, ranging from 50% to 87% (on average 10.6 out of 16 criteria were met). Five studies had a high quality score (>60%). The criteria that were most frequently not met were H (follow-up of at least 6 months) and J (information about completers vs. loss to follow-up/drop outs).

### Synthesis of results

The results are summarized in Table 1. The association between physical symptoms and the outcomes of the nine studies that were included could be combined to form two types of association: the overall association between physical symptoms and the course of MDD (type A) and the association between physical symptoms and adherence to pharmacotherapy and treatment-related adverse effects (Type B). The last column of Table 1 refers to this type of association. An overall level of evidence was determined for both types, and is described in the text below.

Furthermore, a level of evidence was determined for the sub-types that were used to determine the overall level of evidence, namely the association of physical symptoms with respectively: time to a clinically relevant response to treatment, probability of a clinically relevant response, or mean change on a scale measuring depressive symptoms. These levels of evidence are also described below.

#### A. Association between physical symptoms and course of MDD

Six studies reported on the association between physical symptoms and the course of MDD. All six studies reported a negative influence of these symptoms, and two studies [23-24] had a high score for quality in our review. Both reported statistically significant associations. Based on the criteria for determining the level of evidence, the conclusion is that there is strong evidence for a negative overall association of physical symptoms with the course of MDD.

As mentioned above, the overall association between physical symptoms and course of MDD was composed of three subtypes. The level of evidence for each of these subtypes is described below, as well as the strengths of these associations in the individual studies. Two studies [20,21] reported on the influence of physical symptoms on the time to response to treatment, with results pointing in the same direction. A high score on a scale measuring physical symptoms at baseline predicted a 6.2-week longer time to treatment response in one study [20] and a longer time to onset of response in the other [21]. The duration was not specified in the latter study. The level of evidence for the association in terms of time to response, is inconclusive, since one of the studies reported non-significant results [20] and the other study [21] had a low score for quality.

Two other studies [22,23] reported on the influence of physical symptoms on the probability of response to treatment. Both demonstrated that a high score on a scale measuring physical symptoms at baseline predicts a lower probability of a good response. One of the studies [22] reported an OR of 2.29 on an unfavorable course for patients with physical symptoms at baseline. The other study [23] reported a protective OR of a low score on the Symptoms Checklist-90 Revised (SCL-90-R) somatic subscale [30]. This OR is a .96 per point decrease on this scale. Therefore, a decrease, for instance, of 10 points on this scale (ranging between 12 and 60) at baseline already implies a protective OR of .61 on a favorable response. Since the results of both studies are significant, but only one study had a high score for quality [23], the level of evidence is moderate for this association.

Finally, two studies [24,25] described a negative and significant association between physical symptoms and severity of depression at follow-up. One of the studies [24] reported that, for patients with a physical presentation of MDD at baseline, the decrease on a scale measuring the severity of MDD was almost twice as much as for patients with a psychological presentation. The other study [25] reported a beta-coefficient of -.24, implying that a patient who scores, for instance, 10 points higher on the somatic scale of the SCL-90-R could expect a 2.4-point less decrease on the HAMD-17. The level of evidence for the association between physical symptoms and severity of depression is moderate, since one of the studies had a high score for quality and one study had a lower score for quality.

#### B. Association between physical symptoms and adherence to pharmacotherapy and treatment-related adverse effects

Three studies [26-28] reported on the association between physical symptoms and adherence to pharmacotherapy or treatment-related adverse effects. Two studies [27,28] demonstrated a relationship between discontinuation of medication and physical symptoms at baseline. Only one of these studies had a high score for quality [27]. Since both studies reported statistically significant results, the conclusion is that there is moderate evidence for a negative association between physical symptoms and adherence to pharmacotherapy.

One study [26] found that there was no correlation between somatic scores on the SQ-SS and number of
treatment-related adverse effects (TRAEE) but that a greater degree of somatic symptoms at baseline predicted emergence of at least one TRAE reported as moderate or severe. Since this is the only high quality study reporting on this relationship, the evidence remains weak.

**Discussion**

**Summary of evidence**

All studies included in this systematic review indicated a negative effect of physical symptoms on the prognosis of...
MDD. Based on the consistency of this finding across the available studies, the strength of the associations found, and the quality of the studies, the overall level of evidence for this association appears to be strong. The overall association of physical symptoms was sub-divided in two types of association: Type A, which refers to the association between physical symptoms and the outcome of MDD, and Type B, which refers to the association between physical symptoms and adherence to pharmacotherapy for MDD. The evidence for type A association appeared to be strong, and the evidence for Type B association appeared to be moderate. The findings for both types of association, and especially the strong evidence for the overall association of physical symptoms with a poorer prognosis of MDD, are important, given the high comorbidity of physical symptoms with MDD that is reported in the scientific literature [7,8].

Ideally one would like to pool the results of several studies, reporting the size of the effect that concomitant physical symptoms have on the prognosis of depression, but given the small number of studies available and the variety of methods and measures employed, calculating a meaningful overall effect-size was not feasible. However, the available studies do warrant the conclusion that the effect of concomitant physical symptoms is both statistically and clinically meaningful. There is reason to assume that this effect might be substantial. One of the studies [24] reported that for patients with a physical presentation of MDD at baseline the decrease on a scale measuring the severity of MDD was almost twice as much as for patients with a psychological presentation. Two studies [22,23] reported OR on an unfavorable course for patients with physical symptoms at baseline. The first [22] reported an OR of 2.29 (CI 1.13–5.0), The second study [23] used another scale to measure physical symptoms, the somatic scale of the SCL-90-R. An odds ratio over a comparable difference in points on this scale corresponds with an OR of 1.63 (CI 1.27–2.10). The odds ratio thus appears to lie between 1.27 and 5.0, implying that in the studies reporting OR [22,23] the likelihood of an unfavorable course of MDD was somewhere between 1.27 and 5.0 times as high for patients suffering from concomitant physical symptoms than for patients not suffering from such symptoms. This is a rough estimate, but it does show that the effect of physical symptoms on the prognosis of MDD might be quite large. This suggests that difficulty in translating efficacy findings to real-world settings is associated with increased suffering from concomitant physical symptoms in patients with MDD.

Limitations and strengths of the study

Because of the importance of the subject under study, it is somewhat puzzling that we could only find nine studies that met our inclusion criteria. The fact that unpublished studies were not available for consideration might possibly play a role. Studies that did not find the effect we describe might not have been published. Therefore, the conclusion of our best-evidence synthesis, i.e., that there seems to be strong evidence for a negative association between physical symptoms and the prognosis of MDD, is only a first step. Evidently, more studies are needed in order to gain more insight into the phenomenon.

Future studies could focus on effect-modification by physical symptoms of specific types of treatment for MDD. In particular, trials evaluating the effect of physical symptoms on psychotherapy could provide more insight. Studies which include a clinical assessment as to whether or not the physical symptoms that depressed patients experience are medically unexplained would also be welcome. From the studies included in this review we were unable to make such a distinction. An overview of scales to assess physical symptoms, that could be included in baseline questionnaires, is provided by Hiller and Janca [31].

Conclusions and implication for daily practice

Based on our results, a few recommendations can be made for daily clinical practice. Given the evidence for quite strong associations between physical symptoms and subsequent prognosis of depression, comorbid physical symptoms should be assessed systematically in depressed patients. Since both adherence to pharmacotherapy [27,28] and outcome seem to be negatively affected [26], specific attention should be paid to physical symptoms -both explained and unexplained- in patients suffering from depression.

Effective treatment for MDD in the co-occurrence of physical symptoms may require collaboration between different health care professionals. The experiences in primary care with the collaborative care model are promising in this respect, since this method of organizing co-operation between health care professionals has been found to be effective in the treatment of both MDD [32] and persistent medically unexplained symptoms [33].
