Abstract

A descriptive norm is a behavioral rule that individuals follow when their empirical expectations of others following the same rule are met. We aim to provide an account of the emergence of descriptive norms by first looking at a simple case, that of the standing ovation. We examine the structure of a standing ovation, and show it can be generalized to describe the emergence of a wide range of descriptive norms.

Descriptive norms hide in plain sight. While we may not always think of them, they govern many of our day to day interactions: they help guide our fashion choices, our table manners, the colors we wear at weddings, and any number of other small features of our social interactions. This governance can become evident when we travel: many of our small-scale behaviors and interactions are culturally contingent. How Americans use their forks when eating in polite company would seem gauche to Europeans. Standards for personal space vary across cultures. It would be difficult to argue that any one of these practices is ‘right’ – descriptive norms do not carry the normative weight of social or moral norms – but we all follow the norms from our own cultural context. In that sense, the right behavior is simply the behavior that everyone else follows. While this may provide a satisfactory answer to how one ought to act in a given culture, it does not tell us about how these descriptive norms came to be. What is it about a given norm that caused everyone to start following it?

To begin to answer this question, we will turn to a simple case, that of the standing ovation. Standing ovations, like many other descriptive norms, are the result of spontaneous coordination of individual choices across many individuals. They have become a common practice after many live performances, even though there is no pre-arranged plan or even any formal coordination. All individuals can do is decide whether or not they wish to stand, based on their own preferences, and what they see others doing around them. (Miller and Page 2004) Put slightly more formally, most agents have preferences about whether or not they like to stand up, dependent on the quality of the concert. They
know that standing to clap is a common option after a performance, and they have (conditional) preferences for standing up if the other agents stand up, too. This exemplifies a descriptive norm: the agents know that there is a behavioral pattern (standing to clap) that applies to the situation they are in, and they prefer to conform with the group (Bicchieri 2006, 31-32). In other words, their behavior is not only determined by unconditional preferences for certain actions, but also by their desire to conditionally conform to the behavior of a sufficiently large group. We aim to examine how ovations might arise, and in doing so, come to a more general account of the emergence of descriptive norms in a population.

To provide for this more general account, we investigate several features of individual decisions, such as a desire to conform, one’s knowledge of what others are doing, and one’s own preferences. These can affect the emergence of a descriptive norm in a group. These elements influence some aspects of the processes, such as whether the group converges on a single behavior, and if it does, how quickly this happens. Our model allows us to carefully explore the key aspects of individual decision making that drive these collective behaviors.

One additional fact that we wanted to take into consideration was that though descriptive norms can be built out of many small decisions, they do not always occur. While many of our day to day activities are governed by norms, not all of them are. Our model helps us to explore the contingent nature of many descriptive norms. What this model suggests is that it is possible that some descriptive norms become descriptive norms for no particular reason other than the peculiarities of the individuals in the population.

In this paper we explore four main models:

1. In the first one, the baseline, we build a model for a standing ovation, which considers an individual’s decision about whether she will stand to be a combination of her personal unconditional preference and her tendencies to choose to conform to the behavior of others.

2. In the second extension, the inertia model, we introduce two new features of individual decision-making: first, a tendency of individuals to become increasingly set in their ways as time goes on, and second, a more nuanced model of social contagion, to better match how bandwagon effects occur.

3. In the third extension, the endogenous social sensitivity model, we treat one’s sensitivity to the behavior of others not as something separate from one’s individual preferences, but as dependent on them.

4. In the fourth extension, the symmetric model we consider a reversible case, where each agent can decide whether to stand up or to sit down in any round.
Each model helps us learn more about the nature of social decision-making. In light of these models, we can not only distinguish a behavioral norm from a mere behavioral regularity, but we can also better understand the conditions for the emergence of a descriptive norm, as well as the factors that can ultimately inhibit a norm from emerging. Unlike Lewis’ approach to the analysis of conventions, here we focus on the decisions of agents who do not reason about other agents’ expectations, and behavioral rules that themselves have no intrinsic coordination advantages. Instead, we focus purely on the dynamics created by individuals who have both intrinsic preferences to act and some interest in conformity. This allows us to focus on a wider range of more common descriptive norms.

1 The Baseline Model

1.1 Model Description

Let there be $M$ people in the audience of a theater play. The variable $s_i^{(n)}$ with $i = 1, \ldots, M$ indicates whether person $i$ is sitting ($s_i^{(n)} = 0$) or standing ($s_i^{(n)} = 1$) at time-step (“round”) $n = 0, 1, \ldots$. Time is discretized and at $n = 0$, everybody is seated. Everybody who is not yet standing “updates” her position in each round. Our central idea is that whether or not a person stands up depends on her effective propensity to do so. The effective propensity of person $i$ is the convex combination of two factors:

1. An intrinsic preference $q_i$ to stand up. This represents an individual’s preference to stand up or not, independently of what other people are doing.

2. An extrinsic propensity to stand up. This factor takes into account what other people in the audience are doing. So whether or not someone stands up in round $n$ will depend on how many people $S^{(n-1)} := \sum_{i=1}^{M} s_i^{(n-1)}$ were standing up at round $n - 1$. Note that $S^{(0)} = 0$.

Combining these two factors, we arrive at the following expression for the effective propensity to stand up in round $n$:

$$P_i^{(n)} = \sigma_i \left( \frac{S^{(n-1)}}{M} \right) + (1 - \sigma_i) q_i$$

(1)

We see that the variable $\sigma_i \in (0, 1)$ measures how much person $i$ takes the extrinsic propensity, i.e. social considerations into account. It determines the relative weight of intrinsic and extrinsic propensity. Therefore, we say that $\sigma_i$ measures the social sensitivity of person $i$. Let’s call the model in equation (1) the baseline model. In each round $n$, everybody who is still sitting considers her
propensity \( P_i^{(n)} \) and then decides, by a chance mechanism, whether or not to stand up.

Given that \( P_i^{(n)} \) is not a decreasing function of \( n \), the Borel-Cantelli Lemma implies that the number of standing people will converge to 1, as \( n \) goes to infinity. But in practice, only a finite number of rounds will be played, and if the \( \sigma_i \)'s are sufficiently small, it may well be the case that not everyone stands up. In order to better study this model, let us now turn to a numerical analysis of the model.

### 1.2 Numerical Analysis

Our model (and its extensions, which we will discuss below) suggests a variety of numerical studies. In order to best investigate these cases, we turn to instantiating the models as agent-based computer simulations. The simulations were written in Netlogo 4.0.4.

In the agent-based simulations, 1089 agents are seated in a 33x33 grid, all facing the same direction, in order to represent individuals seated in a theater. As is standard in agent-based models, time is broken up into discrete steps. In each step of the simulation, seated agents independently assess whether or not they should stand. Their decision procedure is simply an instantiation of the equation previously described. As was noted before, agents who are standing remain standing in perpetuity. Each simulation is run until either every agent is standing, or 1000 steps have passed. If each step represents one second of actual time, 1000 steps represents nearly 17 minutes, which we consider to be the extreme upper end of how long a standing ovation might last. For the purpose of analysis, all simulations were repeated 100 times.

#### 1.2.1 Complete Information

In our first set of simulations, we examined agents who could see the entire audience. Their position in the theater had no effect on what information was available to them. As such, agents all worked from precisely the same information about what others in the audience were doing.

As we have previously noted, the baseline model guarantees convergence on a standing ovation. So instead of discussing whether or not a standing ovation occurs, we study the speed of convergence. In particular, we are interested in determining how the parameters specified in the baseline model affect convergence times.\(^1\) To examine these effects, we must consider the agents’ intrinsic

\(^1\)For ease of analysis, we report on those models in which all agents have the same parameter values. We examined mixed populations, but did not find differences that merited separate presentation.
propensity to stand up, and the agents’ social sensitivity in turn. We will first examine the effects of the intrinsic propensity on ovation convergence. In our studies of the intrinsic propensity we held social sensitivity $\sigma$, fixed at various values (figure 1) so we could examine how the increase of the intrinsic propensity by itself affected rates of norm convergence. In general we saw that, as the intrinsic propensity increases, the speed of convergence decreases. This is, of course, exactly what we expect from the mathematics of the model (1).

![Figure 1: The effect of intrinsic preference on time to convergence](image)

We found a similar story with an examination of the social sensitivity (figure 2). As before, what we saw is that as the social sensitivity increases the time of convergence decreases. However, the speed of convergence diminishes at a fairly different rate when the social sensitivity is combined with a very low value of intrinsic propensity ($q=0.1$). This makes perfect sense: when both the intrinsic propensity and the social sensitivity are very low, it takes long time until everyone is standing. It is enough that the social sensitivity slightly increases for the initial deadlock to be resolved.

We found that both parameters make a notable difference: each can cause the convergence rate to be significantly faster. However, the manipulation of social sensitivity appears to diminish convergence time more pronouncedly. This makes also sense: sensitivity to one’s peers will accelerate any bandwagon effect as the population moves towards convergence.

### 1.2.2 Incomplete Information

In our second set of simulations, we examined agents who were limited in how much of the audience they could see. In particular, agents could only see the agents in front of them within their range of vision. In this model, agents
could see all the way to the front of the theater, but only within a cone of 30 degrees. Thus, agents could not see anyone behind them, nor anyone outside of this limited scope of vision in front of them. To describe this more formally, consider an audience of \( R \) rows with \( L \) seats in each row. Now everybody takes only a fraction of the whole audience into account when calculating the extrinsic propensity, for example the cone of people in front of the person. Then, clearly, the behavior of the people in the first row will be more important than the behavior of those in the last row. After all, almost everybody will look at what the people in the first row are doing. In this case, the ratio \( S^{(n-1)}/M \) is to be replaced by the expression

\[
\frac{1}{|\mathcal{M}_i|} \sum_{j \in \mathcal{M}_i} s_j^{(n-1)}
\]

(2)

Here \( \mathcal{M}_i \) is the group of people person \( i \) can observe.\(^2\)

In these models, position becomes increasingly important. Agents can observe different sets of people. Also, this introduces an asymmetry between information and influence. Agents in the front rows have very little information about what their peers are doing, but their behavior has a much larger influence on their peers, as their choices are taken into account by agents with seats toward the rear. This model extension helps us represent the idea of social hierarchies in the emergence of norms.\(^3\)

\(^2\)For modeling simplicity, we assume that each agent counts herself as a spectator. In this way, we avoid the issue that the model would otherwise be undefined for agents in the front row. While this is a slightly strange assumption, no result hinges on this claim - it just keeps the model definition simpler.

\(^3\)One notable difference between this representation and the real world is that we represent
As with our study of model of complete information, we first held the social sensitivity parameter fixed at discrete values to study the effects of the intrinsic propensity’s increase (Figure 3). We found that the model with incomplete information behaved very similarly to the complete information case, though convergence times were notably slower at low values of $q_i$. Where in the complete information case, when $q_i = 0.1$ average time to convergence was 20.25, in the case of incomplete information average time to convergence was 59.47. As $q_i$ grew, however, these disparities disappeared.

This suggests that while limited information can have a notable effect in slowing down convergence times in cases of low levels of intrinsic propensities, this effect rapidly diminishes as agents’ intrinsic propensity to stand increases.

![Figure 3: The effect of intrinsic propensity on time to convergence in the limited vision case.](image)

As we turn our attention to the effect of the social sensitivity parameter however, we find that limited vision has a strikingly large effect that reverses the trend seen in the model of complete information (Figure 4). Whereas before, moving $\sigma_i$ from a low to a medium value induced significantly lower convergence times, in the model of incomplete information, as $\sigma_i$ increases, convergence time also increases. Once $\sigma_i > 0.5$ we find particularly dramatic increases in both convergence times and variance. Limited vision of others has a dramatic effect on convergence, and for good reason. As the social sensitivity increases, the effect of the intrinsic propensity diminishes. When this is combined with very few people standing, the process radically slows down. Moreover, the individuals who are most seen by others are those who see the fewest peers themselves. social hierarchies as fixed relationships that shape agent decisions. In the real world, however, agents choose to pay attention to these social hierarchies. We do not address this element of choice in the model.
This can then lead those that look to them for guidance about standing to also remain seated. This dynamic substantially dampens the bandwagon effect that is found in the baseline model with complete information.

![Figure 4: The effect of social sensitivity on time to convergence in the limited vision case.](image)

### 2 Problems with the Baseline Model

While the baseline model helps illuminate the basic structure of individual decisions that can result in the emergence of a descriptive norm such as a standing ovation, there are several reasons to suspect that the model is not yet adequate. We can levy three major criticisms at the baseline model. We will look at each in turn.

The first way in which our model falls short is in the fact that the model is not very sensitive to more a more nuanced psychology of decision-making. One thing it fails to capture is the idea of entrenchment - people can often become set in their ways over time, and become less and less willing to change their minds, even if social influences become significant. Additionally, the baseline model lumps the notion of social sensitivity in with the notion of social contagion: it assumes that larger and smaller groups exert the same amount of social influence over a person’s decision. But it is likely that in some instances, small groups are sufficient for influencing individual choices, while in others, a much larger group is necessary to change an individual’s decision.

The second way in which our model falls short is that it assumes that the amount others can influence us is always constant across decisions. But this is unlikely to be the case. In instances where one has strong preferences, it is likely that
social pressure is less important. Whereas, when someone is fairly indifferent between two actions, social pressure might be the main determinant of that person’s choice.

The third way our model falls short is that it makes significant structural assumptions about the nature of descriptive norms that may inhibit its ability to be a useful general model. This comes in two ways. Most obviously, the model always lead to a convergence on everyone standing. This is a highly suspect assumption: there are many concerts in which standing ovations fail to occur, just as there are many potential descriptive norms that never come to be. Even still, we can expect many situations in which some, but not all, agents take on a particular action, and for this to be stable. As it currently stands, our model cannot capture this fact. Additionally, the model suffers from having a built in implicit assumption about the directionality of norms. In our baseline model, people go from sitting to standing. It is impossible for sitting to become a norm. Likewise, it should be possible for no norm to emerge.

In the following sections, we will present extensions to the baseline model that will in turn seek to address these three deficiencies. What we will show is that the qualitative results from our baseline model continue to hold as we investigate the first two deficiencies. As we explore the structural assumptions, we will find additional constraints on the emergence of descriptive norms that further enrich our account.

3 The Inertia Model

In this extension, we seek to address the lack of nuance in the psychology of the baseline model’s decision procedure. To do this, we make two changes: First, there is a scaling factor $e^{-\alpha n}, 0 < \alpha < 1$ such that the more rounds have passed, the less likely it is that someone stands up. This allows us to more carefully investigate the notion of entrenchment. Second, the propensity to stand up as a function of the others’ behavior is taken into the $\beta$th power, $\beta > 0$. $\beta$ can be thought of as a measure of contagion in the group: The smaller $\beta$ (0 < $\beta$ < 1), the higher the chance that a few isolated individuals who raise from their seats will affect the rest of the group. On the other hand, if $\beta$ increases ($\beta$ > 1), then the others’ behavior affects a decision to stand up only if a vast majority is already standing. Thus, agents with a large $\beta$ act on the basis of their propensity and the observed behavior of a crowd (as opposed to being responsive to the behavior of individuals and small groups). The break-even point is $\beta = 1$. All this can be represented by the following equation:

$$P_i^{(n)} = e^{-\alpha n} \left( \sigma_i \left( \frac{S^{(n-1)}}{M} \right)^\beta + (1 - \sigma_i) q_i \right)$$  (3)
In this model, there is a nontrivial probability that not everyone stands up, even if infinitely many rounds are played.\(^4\) Finally, it should be stressed once more that contagion and social sensitivity play different roles: while social sensitivity balances an agent’s individual preferences against the impact of the behavior of others, the contagion parameter determines whether an agent responds to the behavior of individuals, or only to the behavior of large groups.\(^5\)

### 3.1 Numerical studies

The inertia model is meant to provide a mechanism for non-complete ovations, by providing a countervailing force on individual decision-making, encouraging some to remain seated. This is done with a time-dependent scaling function, which can be made more powerful by increasing the size of the inertia parameter $\alpha$. Secondly, it dampens the effect of social influence - weakening the power of smaller groups, while magnifying the power of large groups, by taking the social sensitivity component of the base model and raising it to the $\beta^{th}$ power. We will investigate each of these modifications to the base model in turn, considering their effect on ovation size in equilibrium.

As the model description indicated, the inertia parameter $\alpha$ has by far the largest effect on ovation size. Here we will consider $\alpha$ with $\beta$ fixed at 0.1. In general as the inertia parameter grows, we find an exponential decay in equilibrium ovation size. We examined values of $0.01 \leq \alpha \leq 0.5$ in steps of 0.01. As represented in figure 5, we find a rapid decay in equilibrium ovation size.

The contagion parameter $\beta$ has a significantly smaller effect on ovation size in comparison with $\alpha$ (figure 6). Where the inertia parameter reduced the size of the ovation by over 90% in the range that we examined, increasing the contagion parameter to its maximum value reduces ovation size by a little more than 50%.

As we can notice from examining figure 6, however, the bulk of the effect of the parameter comes in as $0.01 \leq \beta \leq 1$

So while we find that both $\alpha$ and $\beta$ make significant reductions to ovation size in equilibrium, $\alpha$ makes twice the difference. This again can be explained by thinking about how bandwagon effects occur. The inertia parameter controls the rate at which agents are willing to stand as time goes on, which heavily dampens their ability to respond to new information as it is revealed to them as time goes on. As agents become increasingly stubborn

\(^4\)The $e^{-\alpha n}$ term dominates in the long run and makes $P_i^{(n)}$ approach zero very quickly.

\(^5\)We have also explored a different extension of the model with a counter-force to the overall conformity. This second way assumes that some people increasingly resist standing up as more people stand. They act against the mainstream. We do not present this non-conformist model, as we did not find a significant deviation from the baseline model, even if this condition may be psychologically relevant.
as time goes on, this limits their interest in standing regardless of what anyone else is doing. We find a similar story with the contagion parameter $\beta$ – since individuals respond less to smaller groups, it is more difficult to get a bandwagon effect initiated, even if they are increasingly sensitive to large groups. The large groups simply cannot form if smaller groups do not have sufficient attractive force. In this way, $\alpha$ and $\beta$ work in concert to limit ovation size: $\beta$ limits the power of an initial small group standing, and then $\alpha$ increases the stubbornness of agents sitting as the groups get slightly larger over time. This combined effect can neuter a group’s ability to create a social bandwagon.

In the inertia model, we find that the imposition of incomplete information has very little effect on how the active variables in the model affect ovation size. In the case of $\alpha$, we find no discernible difference between the complete information model and the model of incomplete information. In the case of $\beta$, we find few differences where $0 < \beta < 1$. 

Figure 5: The effect of the inertia parameter on the number of people standing.
4 The Endogenous Social Sensitivity Model

The baseline model and its initial extension, the inertia model, consider social sensitivity as an exogenous parameter: It is a parameter that balances one’s intrinsic propensity to comply with the behavioral rule with the impact of group behavior. In other words, for an agent with high social sensitivity, the impact of group behavior will dominate the impact of one’s individual judgment on the quality of the concert, and vice versa. Social sensitivity does not, on that account, depend on one’s intrinsic propensity or the number of people already following the behavioral rule.

This view can, however, be challenged. In her book “The Grammar of Society”, Bicchieri (2006) has shown that empirical expectations of the behavior of others are crucial to whether descriptive norms emerge and persist. If an agent expects a critical part of the population to follow a behavioral rule, then she will most likely follow the rule as well. If a large part of the group starts to comply with the rule, the agent reasonably expects that the behavior will spread to the entire group, and these expectations overrule an agent’s independent preferences as a determinant of her individual behavior. Conversely, if the percentage of individuals abiding by the rule is lower than such a critical value, group behavior barely affects individual behavior. Social sensitivity should thus be treated as an endogenous variable crucially depending on the observed behavior in the group.

Both in the baseline case and the inertia extension, social sensitivity was considered exogenous. If it is low at the outset, then it will stay low, even if the norm spreads rapidly in the group. This delays the convergence process. It
is therefore worthwhile to investigate whether our results remain robust under the feedback effects described above. To that end, we have to specify the dependency between the variables of the original model.

We keep the baseline equation (1) intact and only write social sensitivity $\sigma$ as a function of the other variables.$^6$ As argued above, social sensitivity should be very low ($\approx \varepsilon$) if $S/M$ is significantly below a critical value, and very high ($\approx 1$) if $S/M$ significantly exceeds that value. It is natural to assume that the lower the intrinsic propensity $q$, the higher the threshold: If an agent strongly dislikes the behavioral rule, her empirical expectations of compliance with the rule will be higher, and the group will have to behave more homogenously in order to meet them. Thus, we might choose

$$\sigma \left( \frac{S}{M} \right) = \begin{cases} 1, & \text{if } S/M \geq 1 - q, \\ \varepsilon, & \text{otherwise.} \end{cases}$$

(4)

Figure 7 below gives a graphic representation of the model. On the $x$ axis is the number of people standing up on the total audience, on the $y$ axis the values of $\sigma$.

![Figure 7: Discontinuous Model](image)

The higher the intrinsic propensity $q$ of an individual $i$ to stand up, the lower the number of people standing up - $S/M = (1- q)$ - necessary to "activate" an individual’s social sensitivity. As the intrinsic propensity increases, the number of people standing up necessary for $\sigma$ being equal to one decreases.$^7$

$^6$This implies that $\sigma$ is time- and agent-dependent, but for reasons of simplicity, we drop the subscripts in this exposition.

$^7$It is, however, not clear whether real social sensitivity is as discontinuous as this equation suggests. It seems more realistic that in many cases people have moderate individual preference coupled with moderate social sensitivity. So we “smooth” the function by introducing an additional parameter that governs the quickness of the transition. We did not find that this variation had a significant difference on the final result, so we only report on the discontinuous case, as the mathematics are more straightforward.
4.1 Numerical Studies

In this set of simulations, we studied the effect of the intrinsic propensity on time of convergence. We examined values of $q$ varying from 0.01 to 1 in steps of 0.01. For simplicity of our treatment, we do not introduce the inertia and contagion parameters, as we have previously examined them in isolation. Further, as we didn’t find crucial differences between the incomplete and the complete information case, we only present the first case. As expected, and the figure below shows, we find that the time of convergence decreases for increasing values of intrinsic propensity. As in the baseline model, also in this case we see that the time of convergence decreases more quickly for lower values of $q$. The rationale of this result is that for higher and higher values of intrinsic propensity, the ovation tends to spread in the population, not unlike a social bandwagon effect.

![Figure 8: The effect of the endogenous sigma on the number of people standing](image)

5 The Symmetric Model

In our final model, we consider a generalization of our original model. As we have previously discussed, the models we have been considering thus far all have an implicit directionality: people start out sitting, and potentially stand. The only descriptive norm that can emerge is one of ovation. But this assumption limits our ability to describe the emergence of descriptive norms more generally. As an example, consider the norm that governs how forks are used while eating. In Europe, a fork is used in the left hand, so as to enable the eater to use a knife in her right hand. In the United States, however, while forks are held in one’s left hand while cutting food, they are then moved to the right hand for raising
food to one’s mouth. While either method of using forks is perfectly suitable for consuming food in a polite and efficient manner, they are regionally segregated. In the United States, it is rare to see the European method, and the US method is rarely seen in Europe. What we can notice is that there is no particular reason to think that one method is prior to the other, so we cannot model this as a standing ovation. So how might we provide an explanatory framework for the emergence of norms when the potential behaviors are on equal footing?8

What we propose is a return to our baseline model (1), but with a few crucial changes. First, we introduce two agent types, each type having a preference for one of the two actions available to them. So type 1 agents prefer action 1, and type 2 agents prefer action 2. Second, we re-interpret the variable $0 < q < 1$, such that 0.5 represents the indifference point, rather than 0. On this new interpretation, 1 represents a strong preference for the action of one’s type, and 0 represents a strong preference away from this action. Third, we allow agents to change their minds: whereas in previous models once an agent has chosen to stand, she must remain standing, in this model agents can reverse course and go back to their previous action. Finally, when we initialize the model, agents are randomly (and independently) assigned an initial starting action. So, unlike previous models, our starting state has half of the agents performing the first action (say, the European way of using forks), and half the agents performing the second action (like the US method of using forks).

These changes allow us to investigate several things that could not be examined in previous models. In particular, since we are treating the two methods of using forks as symmetrical to each other, and we allow agents to change their minds, we should expect the models to be more dynamic. More importantly, however, we are now able to clearly separate cases of norm emergence from behavioral regularities, since we have differing preferences amongst agents.

The model’s equilibrium states can be broken down into three classes: descriptive norm emergence, large-scale behavioral regularities, and a mix of behaviors. Descriptive norm emergence is found when the entire population settles on a single action. In these cases, half of the population must be going against their intrinsic preferences, and instead their social sensitivity drives their decision-making. This can be contrasted against large-scale behavioral regularities, which are cases in which all agents of one type choose the same action, but choose a different action from agents of another type. So everyone who prefers European fork handling employs it, and likewise everyone who prefers US fork handling does so. In this case, we claim that individual preferences are the most pow-

---

8Peyton Young (2009) develops a model of innovation diffusion that assumes priority of one action over another, that shares some characteristics with Schelling (1971). While this model is rather elegant, it does not capture the possibility of equal footing for either norm, or the possibility of no norm emerging.
eful guide to decision-making, and so social sensitivity effectively drops out of consideration. Our final case is what is left over: a mix of influences, none of which is strong enough to completely guide behavior. In these cases, both preferences and social sensitivity are at work, neither of which is sufficiently strong to overpower the other. So we find an unsystematic mix of behaviors. Let us now turn to a more careful numerical analysis of this model.

5.1 Numerical Studies

This model requires a different approach to our analysis. Rather than consider something like time to convergence, we must instead consider the probabilities of settling into the three different states for the different values of intrinsic preference and social sensitivity. The initial state is shown in the figure below, as it appears in the Netlogo interface. The grid represents the theatre audience, composed by two agent types: squares are agents who prefer sitting and circles are agents who prefer standing. White circles stay for those agents who perform their preferred action, in this case sitting, otherwise they are black. Black squares stay for those agents who perform their preferred action, namely standing, otherwise they are white.

Figure 9: Symmetric Model’s Initial State

In the set of simulations for the symmetric model we examined the probability for a norm to emerge according the distributions of social sensitivity and intrinsic propensity between the audience. The norm emergence corresponds to a state in which all agents in the audience perform the same action, regardless of their intrinsic propensity. Graphically (figure 10), this happens when all circles and squares are white (or when all circles and squares are black). What we found was that the emergence of full descriptive norms is quite rare: only when social sensitivity is much stronger than intrinsic preferences do we find descriptive norms reliably emerge.
What we found was that the emergence of full descriptive norms is quite rare: only when social sensitivity is much stronger than intrinsic preferences do we find descriptive norms reliably emerge.

More common are large-scale behavioral regularities. These occur when agents perform their favorite action (figure 13), e.g. when all squares are standing and all (figure 13) circles are sitting. These outcomes can happen for wider ranges of social sensitivity, so long as the intrinsic preference is more extreme in value. Most common of all, however, are mixed outcomes, those in which some of the agents perform their preferred outcome and others don’t (graphically, this correspond to a situation similar to the initial state but with a different distribution of colors, according to those circles and square that modified their initial state).

This result seems to comport well with the real world: though descriptive norms are quite common and are found in a very wide variety of social situations, there
Figure 12: Behavioral Regularities

Figure 13: The probability of behavioral regularities emergence

are many more possible descriptive norms than there are actual descriptive norms. Most of our day to day behaviors are not norm-governed, even though many are.

6 Conclusions

We have argued that a model of standing ovations can provide a useful framework for the investigation of the emergence of descriptive norms. While we do not claim that all descriptive norms have the character of standing ovations, we have tried to suggest that with a few modifications, we can transform a model of standing ovations into a fully general model of the emergence of descriptive norms. In particular, we wish to stress the qualitative match of results across the various models we present. The baseline, inertia, and endogenous social
sensitivity models all explore the convergence dynamics of a ‘directed’ transition from one behavior to another. Though they build in substantively different psychological assumptions about the agents involved, we find that these large perturbations do not shift us far away from our original baseline results.

While descriptive norms themselves most often are not fully captured by the baseline model, it can often be the case that these sorts of directed transitions can describe the propagation of information about the social context for behaviors. For example, Christians remove hats in Church to show proper deference, but not at sporting events. When they enter a novel environment, for which they may or may not have to signal deference – say, going into a classroom or a museum for the first time – they may look to others for signals of what they should do. When we enter into a novel situation, we may not be sure which of our already-established norms ought to govern our behavior. A directed transition model, like a standing ovation, might be a good representation of this sort of phenomenon.

The final model we consider, we contend, does capture the essential elements of the emergence of descriptive norms. What is so striking about this last model is that it is only a minor modification of the original baseline model, but provides a dynamic that much more fully displays the relevant considerations for the potential emergence of a descriptive norm. We did not do anything to change the fundamental decision procedure – we simply allowed people to change their minds, and have preferences for more than one action. But with these small changes, we greatly generalized the model, and enabled ourselves to discuss a much larger class of social phenomena.

This kind of modeling offers some insights into the nature of descriptive norms that might be difficult to arrive at otherwise. In particular, what we find, especially by studying our symmetric model, is that whether a norm emerges at all, let alone which norm it is, is remarkably contingent on factors that have nothing to do with the substance of the norm itself. Whether it is table manners or audience behaviors, or even how we dress, we do not follow them because they are somehow superior to their alternatives, but rather we follow them because a mix of social and personal factors happened to nudge us in one direction rather than the other. We often place value in these norms – Americans are frequently mocked for their fork handling by their European friends – but we should avoid making the mistake that this value comes from the action itself. Rather, we can see the value of an action coming from the fact that we have become accustomed to doing it.
Acknowledgements

We would like to thank the NWO for funding our joint project "Formal Social Epistemology" through an Internationalization Grant (2009-2011). The participants in a workshop of the members of this network as well as the participants of the conference "Future of Philosophy of Science" (Tilburg, 14-16 April 2010) provided useful suggestions and criticisms, for which we thank them.
