Ian Crawford¶, Bram De Rock¶¶ and Frederic Vermeulen¶¶

July 2012

Abstract

Sharp nonparametric bounds are derived for Hicksian compensating and equivalent variations. These “i-bounds” generalize earlier results of Blundell, Browning and Crawford (2008). We show that their e-bounds are sharp under the Weak Axiom of Revealed Preference (WARP). They do not require transitivity. The new i-bounds are sharp under the Strong Axiom of Revealed Preference (SARP). By requiring transitivity they can be used to bound welfare measures. The new bounds on welfare measures are shown to be operationalized through algorithms that are easy to implement.

1 Introduction

Demand analysis is a powerful tool for the measurement of the behaviour and distributional effects of price and income changes. A policy maker may, for example, be interested in the impact on the consumer’s well-being of an introduction of a tax on the fat content of food or of a change in the indirect taxes on gasoline. The common characteristic of such taxes is that they change the relative prices faced by the consumer. How the consumer reacts to this, by choosing an alternative consumption bundle, is subject of the analysis of demand behaviour. Typically the researcher estimates the unknown parameters of a parametric demand system and uses these estimates to calculate pre- and post-reform demands and associated indirect utilities (see, for example, Banks, Blundell and Lewbel, 1997). Comparing these indirect utilities then allows the econometrician to evaluate the impact of the policy reform on the consumer’s well-being. One particularly useful cardinalization of the indirect utility function is Samuelson’s (1974) money metric indirect utility function, which allows one to express the change in well-being in monetary units. Depending on the base price that is used in the analysis, this approach leads to the well-known compensating variation (base price equals the post-reform prices) and equivalent variation (base price equals pre-reform prices) that were proposed by Hicks (1939).

A major disadvantage of standard demand and welfare analyses is that they rely on the functional specification of the indirect utility function that is used. An alternative way to analyze policy reforms is based on the revealed preference (RP) approach, whose foundations were laid down by Samuelson (1938, 1948), Houthakker (1950), Afriat (1967), Diewert (1973) and Varian (1982). The RP approach makes use of methods from finite mathematics, which translate conditions for rational consumption behaviour into testable implications which do not depend on any assumptions about the specification of the consumer’s demand system or the particular representation of her rational preferences. The major disadvantage of the RP approach, however, is that the predictions of demand responses derived from its restrictions are set-valued, i.e. it is only possible to recover bounds on predicted demands.

As a response Blundell, Browning and Crawford (2003, 2008) proposed blending these two approaches by combining Engel curve estimation with RP conditions. This has shown to be a productive technique. Firstly, it makes the RP conditions applicable to the types of datasets which are widely available to researchers (such as the Family Expenditure Survey from the UK or the Consumption Expenditure Survey from the US). Secondly, the approach is easy to implement and therefore contributes to the practical usefulness of RP conditions. Finally, and principally, it allows for empirical RP analysis with substantial discriminatory and forecasting power.\(^1\)

However, whilst Blundell, Browning and Crawford (2008) showed how to improve bounds on the demand responses to price changes, they did so without fully exploiting all of the empirical implications of rational preferences. Indeed, transitivity is not required for their e-bounds. We show that e-bounds are sharp under the Weak Axiom of Revealed Preference (WARP). Further improvements are, in general, possible if preferences can also be assumed to satisfy transitivity.\(^2\) That is if preferences satisfy the Strong Axiom of Revealed Preference (SARP).

For welfare calculations transitivity is, in general, required. This is because non-transitivity can lead to cycles and path-dependence if one attempts to integrate back to utility constant welfare measures. In this paper, we extend the results of Blundell, Browning and Crawford (2003, 2008) to derive sharp bounds on predicted demand responses and on welfare calculations under SARP.\(^3\) These bounds are “sharp for SARP”. For reasons which will become clear we refer to these bounds as “iterated bounds”, or i-bounds. We also show how the method originally presented in Blundell, Browning and Crawford (2003) can be adapted to provide sharp nonparametric bounds on compensating and equivalent variations.

For compactness, we will only present and discuss theoretical results in our following exposition. However, as we will also indicate, these results imply an easy-to-implement method for defining tightest (iterated) bounds on Marshallian demands and compensating and equivalent variations. Evidently, bringing this method to observational data necessarily requires dealing with empirical issues such as measurement error and (un)observed heterogeneity. Here, we can refer to Blundell, Browning and Crawford (2003, 2008) and Blundell, Kristensen and Matzkin (2010); these authors propose methodological extensions for dealing with these issues that are directly applicable to the method we introduce below.

The rest of the paper unfolds as follows. In Section 2, we introduce our iterated bounds on the Marshallian demands for any number of goods, and we provide an easily implemented method for computing these bounds. In Section 3, we introduce the corresponding method for identifying the tightest bounds on compensating and equivalent variations.

## 2 Iterated bounds on Marshallian demands

To set the stage, we first briefly recapture the concept of e-bounds introduced by Blundell, Browning and Crawford (2008, henceforth BBC (2008)). Subsequently, we take the sequential maximum power

---

\(^1\) See Blundell (2005), Blundell, Browning and Crawford (2007) and Blundell, Kristensen and Matzkin (2010) for recent contributions that build further on the basic insights of Blundell, Browning and Crawford (2003, 2008).

\(^2\) Note that in situations in which there are only two goods transitivity adds no further restrictions to the weak axiom (see Rose, 1958).

\(^3\) In terms of RP restrictions, the recovery of demand responses under Walras’ Law, homogeneity of degree zero and negative semi-definiteness of the Slutsky matrix is equivalent to imposition of the Weak Axiom of Revealed Preference (WARP), whereas the requirement that these demands are consistent with full rationality amounts to the Strong Axiom of Revealed Preference (SARP) (see Kihlstrom, Mac-Colell and Sonnenschein, 1976).
path idea for constructing bounds on welfare measures developed in Blundell, Browning and Crawford (2003, BBC (2003)) and use this to introduce the notion of iterated bounds on Marshallian demands. We present an example to demonstrate that these bounds can be used to improve upon the e-bounds if there are more than two goods. Given this result, we next show that our iterated bounds procedure leads to tightest bounds on Marshallian demands. We end this section by presenting an algorithm to compute the iterated bounds. As we will indicate, this algorithm essentially iterates a procedure originally proposed by BBC (2003), which explains the name “iterated bounds”.

### 2.1 E-bounds

We assume $2.1$ E-bounds to compute the iterated bounds. As we will indicate, this algorithm essentially iterates a procedure that generates demands that are consistent with utility maximization. In RP terms, this implies the following assumption.

**Assumption 1 (uniqueness of demands)** For each consumer there exists a set of (nonnegative) Marshallian demand functions $q(p, x)$ for prices $p \in \mathbb{R}_+^J$ and income $x \in \mathbb{R}_+$. Following BBC (2008), we assume uniqueness of demands.

Consider a set of $T$ price vectors $\{p_t\}_{t=1}^T$; we say there are $T$ observations. For a given price vector $p_t$ we denote the $J$-valued demand associated with income $x$ as $q_t(x)$, and we refer to the function $q_t$ as the expansion path that corresponds to the prices $p_t$. Again, we follow BBC (2008) by assuming weak normality of $q_t$.

**Assumption 2 (weak normality)** If $x > x'$, then $q_t(x) \geq q_t(x')$ for all $p_t$.

BBC (2008) address the following question: “Given a new budget $\{p_N, x_N\}$ and a set of observed prices and expansion paths $\{p_t, q_t(x)\}_{t=1}^T$, what values of $q_N$, which exhaust the budget (i.e. $p_Nq_N = x_N$), are consistent with these observed demands and utility maximization?” Let us denote the bundles that exhaust the new budget $\{p_N, x_N\}$ by $B(p_N, x_N) = \{q_N \in \mathbb{R}_+^J | p_N'q_N = x_N\}$.

To state BBC (2008)’s answer to their question, we first need to introduce some revealed preferences (RP) concepts. We start by defining direct revealed preference relations $R^0$.

**Definition 1 (direct revealed preference)** If at prices $p_t$ and income $x_t$ the consumer chooses $q_t(x_t)$ and $p_t'q_t(x_t) \geq p_t'q_t(x_s)$, then $q_t(x_t) R^0 q_t(x_s)$.

Transitivity of preferences then leads to the next concept of indirect revealed preference relations $R$.

**Definition 2 (indirect revealed preference)** If we have a sequence $q_t(x_t) R^0 q_u(x_u) R^0 q_v(x_v) \cdots R^0 q_w(x_w) R^0 q_u(x_u)$, then $q_t(x_t) R q_u(x_u)$.

In our following exposition, we will consider two consistency conditions for utility maximizing consumer behaviour: the Weak Axiom of Revealed Preference (WARP) and the Strong Axiom of Revealed Preference (SARP). It is well-known that SARP is a necessary and sufficient condition for utility maximization, while WARP is only a necessary condition (see Varian, 1982 and 2006, for a detailed discussion).

**Definition 3 (WARP and SARP)**

(i) The demands $q_t(x_t), t = 1, \ldots, T$, satisfy WARP if $q_t(x_t) R^0 q_s(x_s)$ and $q_t(x_t) \neq q_s(x_s)$ then not $q_t(x_t) R^0 q_s(x_s)$ for any $s$ and $t$.

(ii) The demands $q_t(x_t), t = 1, \ldots, T$, satisfy SARP if $q_t(x_t) R q_s(x_s)$ and $q_t(x_t) \neq q_s(x_s)$ then not $q_t(x_t) R^0 q_s(x_s)$ for any $s$ and $t$.

Because WARP only uses direct revealed preference relations $R^0$, while SARP focuses on indirect revealed preference relations $R$ (so exploiting transitivity of preferences), we obtain that SARP is a stronger condition than WARP. As in BBC (2008), we will assume that the expansion paths $q_t(x)$ generate demands that are consistent with utility maximization. In RP terms, this implies the following assumption.
Assumption 3 (SARP) The demands \( q_t(x), t = 1, \ldots, T \) and \( x \in \mathbb{R}_{++} \), satisfy SARP.

To formalize their notion of e-bounds, BBC (2008) use the concept of intersection demands. To facilitate our following comparison of BBC (2008)’s e-bounds with our iterated bounds, we here introduce these intersection demands in a slightly different way, i.e. in terms of intersection incomes.

Definition 4 (intersection income) The intersection income \( \hat{x}_t \), for \( t \in \{1, \ldots, T\} \), is the maximal income for which

\[
\forall q_N \in B(p_N, x_N) : q_N R^0 q_t(\hat{x}_t).
\]

The assumptions of uniqueness and normality ensure that each intersection income \( \hat{x}_t \) is uniquely defined. More precisely, it is the income level such that \( p^*_N q_t(\hat{x}_t) = x_N \). BBC (2008) refer to the corresponding value of the expansion path, \( q_t(\hat{x}_t) \), as the intersection demand for observation \( t \).

Given all this, BBC (2008) define the support set

\[
S^{BBC}(p_N, x_N) = \left\{ q_N : q_N \in B(p_N, x_N) \right\};
\]

and they label the bounds on demand responses that are based on \( S^{BBC}(p_N, x_N) \) as e-bounds.

To end this section, we present a specific characterization of the support set \( S^{BBC}(p_N, x_N) \). As we will explain, this characterization will directly motivate our following research question, i.e. define “iterated bounds” that improve upon the e-bounds. Essentially, the next proposition distinguishes between two cases for \( q_N \in S^{BBC}(p_N, x_N) \): either \( q_N \) is different from the intersection demand \( q_t(\hat{x}_t) \) for any observation \( t \), or we have \( q_N = q_s(\hat{x}_s) \) for some observation \( s \). The Appendix contains the proofs of all our results.

Proposition 1 (profitable characterization of \( S^{BBC}(p_N, x_N) \)) For any \( q_N \) in the budget set \( B(p_N, x_N) \), we have that \( q_N \) is in the support set \( S^{BBC}(p_N, x_N) \) (i.e. meets the e-bounds) if and only if

(i) \( \forall t \in \{1, \ldots, T\} : p'_N q_t(\hat{x}_t) < p'_N q_N \), or
(ii) \( \exists s \in \{1, \ldots, T\} : q_N = q_s(\hat{x}_s) \), and then \( p'_N q_t(\hat{x}_t) < p'_N q_N \) for all \( t \in \{1, \ldots, T\} \setminus \{s\} \).

Inspection of Proposition 1 reveals that the definition of e-bounds nowhere exploits transitivity of preferences, which is captured by the indirect revealed preference relations \( R \). Specifically, any \( q_N \in S^{BBC}(p_N, x_N) \) can be characterized in terms of direct revealed preference relations \( R^0 \), i.e. it satisfies

\[
p'_N q_t(\hat{x}_t) = x_N = p'_N q_N \quad \text{(i.e. } q_N R^0 q_t(\hat{x}_t)))
\]

which follows from the definition of the intersection demands, and

\[
p'_N q_t(\hat{x}_t) < p'_N q_N \quad \text{(i.e. not } q_t(\hat{x}_t) R^0 q_N),
\]

which follows from Proposition 1. Putting it differently, e-bounds only use the empirical restrictions that are implied by WARP consistency. However, as indicated above, utility maximizing behaviour requires SARP consistency, which generally involves further restrictions than WARP consistency. Therefore, in what follows we will define iterated bounds that do fully exploit the restrictions implied by transitivity of preferences. Essentially, this will require generalizations of the concepts intersection income and intersection demand that are based on the relations \( R \) (instead of \( R^0 \)).

### 2.2 I-bounds

We define iterated bounds, or i-bounds, as bounds on demand responses based on a support set \( S(p_N, x_N) \) that accounts for all possible incomes \( x_t \) (rather than only \( \hat{x}_t \)), i.e.

\[ ^4 \text{Note that we make the (implicit) assumption that every observation } t \text{ corresponds to a different intersection demand } q_t(\tilde{x}_t). \text{ Dropping this assumption is actually straightforward, but it would substantially complicate the statement of Proposition 1 without really adding new insights. A similar qualification applies to Proposition 2.} \]

\[ ^5 \text{In this respect, one may also state that E-bounds are best WARP-based bounds but not best SARP-based bounds.} \]
\[ S(p_N, x_N) = \left\{ q_N : \{p_N, p_t; q_N, q_i(x_t)\}_{t=1,\ldots,T} \text{ satisfy SARP} \right\}. \]

Because this set \( S(p_N, x_N) \) considers all demands on the expansion paths \( q_t \), it is the tightest (i.e., smallest) SARP-based support set by construction. In turn, this implies that i-bounds are tightest following the notion of most informative income.

To before, we will refer to the associated value of the expansion path, \( \text{algorithm to compute } \).

Fortunately, as we will discuss in Section 2.3, we can define an easy-to-implement (finite and efficient) alternative. In contrast to intersection incomes, there is no closed formula for computing most informative incomes. Fortunately, as we will discuss in Section 2.3, we can define an easy-to-implement (finite and efficient) algorithm to compute \( \hat{x}_t \) by iterating the procedure for computing the intersection incomes. Analogous to before, we will refer to the associated value of the expansion path, \( q_t(x_t) \), as the most informative demand for observation \( t \).

The next proposition provides a characterization of the set \( S(p_N, x_N) \) that parallels the one of \( S^{BBC}(p_N, x_N) \) in Proposition 1. It also provides a specific definition of \( S(p_N, x_N) \) in terms of the most informative incomes \( \hat{x}_t \). In practical applications, this allows for constructing the set \( S(p_N, x_N) \) once these most informative incomes have been identified.

**Definition 5 (most informative income)** The most informative income \( \hat{x}_t \), for \( t \in \{1, \ldots, T\} \), is the maximal income for which

\[ \forall q_N \in B(p_N, x_N) : q_N R^0 q_u(x_u) R^0 q_u(x_v) \ldots R^0 q_u(x_w) R^0 q_t(x_t), \]

i.e. there exist \( x_u, x_v, \ldots, x_w \) such that \( q_N R^0 q_u(x_u) R^0 q_u(x_v) \ldots R^0 q_u(x_w) R^0 q_t(x_t) \).

This concept of most informative income extends the earlier notion of intersection income by using indirect revealed preference relations \( R \) instead of (only) direct revealed preference relations \( R^0 \). Because the relations \( R \) include the relations \( R^0 \) by construction, we obtain \( \hat{x}_t \geq \hat{x}_t \). Like before, the assumptions of uniqueness and weak normality make that most informative incomes \( \hat{x}_t \) are uniquely defined. However, in contrast to intersection incomes, there is no closed formula for computing most informative incomes. Fortunately, as we will discuss in Section 2.3, we can define an easy-to-implement (finite and efficient) algorithm to compute \( \hat{x}_t \) by iterating the procedure for computing the intersection incomes. Analogous to before, we will refer to the associated value of the expansion path, \( q_t(x_t) \), as the most informative demand for observation \( t \).

The next proposition provides a characterization of the set \( S(p_N, x_N) \) that parallels the one of \( S^{BBC}(p_N, x_N) \) in Proposition 1. It also provides a specific definition of \( S(p_N, x_N) \) in terms of the most informative incomes \( \hat{x}_t \). In practical applications, this allows for constructing the set \( S(p_N, x_N) \) once these most informative incomes have been identified.

**Proposition 2 (profitable characterization of \( S(p_N, x_N) \))** For any \( q_N \) in the budget set \( B(p_N, x_N) \), we have that \( q_N \) is in the support set \( S(p_N, x_N) \) (i.e. meets the tightest bounds) if and only if

(i) \( \forall t \in \{1, \ldots, T\} : p_t'q_t(\hat{x}_t) < p_t'q_N \), or

(ii) \( \exists s \in \{1, \ldots, T\} : q_N = q_s(\tilde{x}_s) \) and then \( p_t'q_t(\tilde{x}_t) < p_t'q_N \) for all \( t \in \{1, \ldots, T\} \setminus \{s\} \).

We conclude this section by Example 1, which demonstrates that BBC (2008)'s support set \( S^{BBC}(p_N, x_N) \) (yielding e-bound on demand responses) need not coincide with the smallest SARP-based support set \( S(p_N, x_N) \) (yielding iterated or tightest bounds on demand responses). The example also illustrates the central intuition behind this result. Specifically, it presents expansion paths where, for some \( t \) (\( t = 1 \) in Example 1), the most informative income \( \hat{x}_t \) is strictly above the intersection income \( \hat{x}_t \), which implies that there exists \( q_N \) with \( q_N R q_t(\hat{x}_t) \) but not \( q_N R^0 q_t(\hat{x}_t) \). Because the set \( S(p_N, x_N) \) must satisfy SARP, this yields the restriction \( p_t'q_t(\hat{x}_t) < p_t'q_N \), which is stronger than \( p_t'q_t(\hat{x}_t) < p_t'q_N \) (because \( \hat{x}_t > \hat{x}_t \)). In turn, this effectively excludes from the set \( S(p_N, x_N) \) some \( q_N \) that belongs to the set \( S^{BBC}(p_N, x_N) \). This demonstrates that, in general, we can have \( S(p_N, x_N) \not\subseteq S^{BBC}(p_N, x_N) \).

As a final note, we emphasize that we need more than two goods for \( S(p_N, x_N) \not\subseteq S^{BBC}(p_N, x_N) \). Indeed, as indicated above, the support set \( S^{BBC}(p_N, x_N) \) exploits the empirical restrictions implied by WARP consistency. And it is well-known that WARP and SARP have the same empirical content if there are only two goods (see Rose, 1958), so that we always get \( S(p_N, x_N) = S^{BBC}(p_N, x_N) \) in this case.

**Example 1** We consider the support set \( S^{BBC}(p_N, x_N) \) for \( p_N = (3, 2, 4) \) and \( x_N = 15 \). Suppose we observe two expansion paths \( q_1 \) and \( q_2 \), which are associated with the prices \( p_1 = (4, 3, 2) \) and \( p_2 = (2, 4, 3) \).
Suppose we have the intersection incomes $\tilde{x}_1 = 13.5$ and $\tilde{x}_2 = 15.8$, with corresponding intersection demands

$$q_1(\tilde{x}_1) = (2, 0.5, 2) \text{ and } q_2(\tilde{x}_2) = (2.3, 2.05, 1).$$

Next, we assume the following most informative incomes. Let $\tilde{x}_1 = 15 > \tilde{x}_1$, with

$$q_1(\tilde{x}_1) = (2, 1, 2),$$

while $\tilde{x}_2 = \tilde{x}_2$ and, thus, $q_2(\tilde{x}_2) = q_2(\tilde{x}_2)$. We remark that an expansion path $q_1(x_1)$ containing both $q_1(\tilde{x}_1)$ and $q_1(\tilde{x}_1)$ does not conflict with our earlier assumptions.

We can then show that $S(p_N, x_N) \subseteq S^{BBC}(p_N, x_N)$. To obtain the result, it suffices to show that there exists $q_N$ with

$$q_N \in S^{BBC}(p_N, x_N) \text{ and } q_N \notin S(p_N, x_N).$$

For the current example, this applies to $q_N = (1, 2, 2)$ (which effectively meets $p_N^T q_N = x_N$). First, we can verify that $q_N \in S^{BBC}(p_N, x_N)$: the demands $q_N, q_1(\tilde{x}_1), q_2(\tilde{x}_2)$ satisfy SARP (with $q_N R^0 q_2(\tilde{x}_2)$ $R^0 q_1(\tilde{x}_1)$). On the other hand, we also obtain $q^0 \notin S(p_N, x_N)$: the demands $q_N, q_1(\tilde{x}_1), q_2(\tilde{x}_2)$ do not meet SARP, which a fortiori implies $q_N \notin S(p_N, x_N)$; in particular, we get $q_N R^0 q_2(\tilde{x}_2) R^0 q_1(\tilde{x}_1) R^0 q_N$.\(^6\)

### 2.3 An algorithm for computing most informative incomes

The following algorithm uses the approach in BBC (2003) to define the most informative incomes $\tilde{x}_1, \ldots, \tilde{x}_T$ and, thus, also the corresponding demands $q_1(\tilde{x}_1), \ldots, q_T(\tilde{x}_T)$.

**Algorithm 1 (computing most informative incomes)**

**Input:** $\{p_N, x_N\}$ and $\{p_1, \ldots, p_T; q_1(\tilde{x}_1), \ldots, q_T(\tilde{x}_T)\}$.

**Output:** $\tilde{x}_1, \ldots, \tilde{x}_T$.

**Step 0:** Set $s = 0$ and $F_s = \{x_1, \ldots, x_T | p_N^T q_1(x_1) = x_N, \ldots, p_T^T q_T(x_T) = x_N\}$.

**Step 1:** Set $F_{s+1} = \{\arg \max_{x_t \in F_s}(x_t = p_i^T q_1(x)), \ldots, \arg \max_{x_t \in F_s}(x_t = p_T^T q_T(x))\}$.

**Step 2:** If $F_{s+1} \equiv F_s$ then set $\{\tilde{x}_1, \ldots, \tilde{x}_T\} = F_{s+1}$ and stop. Else set $s = s + 1$ and go to Step 1.

Note that Step 0 of this algorithm delivers the intersection incomes $\tilde{x}_t$, which BBC (2008) originally considered to define their e-bounds on Marshallian demands. To define our most informative incomes $\tilde{x}_t$ (and so e-bounds on Marshallian demands), we iterate this procedure in Steps 1 and 2. This iteration implies that most informative incomes may effectively exceed intersection incomes (i.e. $\tilde{x}_t > \tilde{x}_t$). As explained in our discussion of Example 1, such an instance effectively obtains $S(p_N, x_N) \subseteq S^{BBC}(p_N, x_N)$.

The following lemma states two important properties of Algorithm 1.

**Lemma 1**

(i) Algorithm 1 converges in a finite number of steps.

(ii) For any $x_t$ we have $q_t(\tilde{x}_t) \geq q_t(x_t) \Leftrightarrow q_N R q_t(x_t)$ for any $q_N \in S(p_N, x_N)$.

Property (i) shows that the algorithm is feasible in finite time, which is a minimal requirement for practical applicability. Next, property (ii) states that each demand $q_t(\tilde{x}_t)$ represents the 'highest point' on the expansion path $q_t$ that is revealed worse than any bundle in the support set $S(p_N, x_N)$.

Two further remarks are in order. First, our earlier assumptions ensure that any income level computed in Step 1 of Algorithm 1 is uniquely defined. As such, computing any set $F_{s+1}$ is straightforward. Moreover, one can show that the worst case complexity of this algorithm is $T^3$, which makes that the algorithm is efficiently implemented.\(^7\)

\(^6\)For completeness, we add that the set $S(p_N, x_N)$ is not empty, as is easily verified.

\(^7\)For the sake of brevity, we do not include a formal proof of this statement here, but it is available upon request.
Second, it is interesting to note that Algorithm 1 can also be used to extend the ‘best’ SARP-based test that was originally proposed by BBC (2003). Specifically, using information on expansion paths \( q_t (t = 1, \ldots, T) \), these authors define a best possible test for SARP consistency of a particular quantity bundle \( q_N (x_N) \) (with \( N \in \{1, \ldots, T\} \)) that is conditional on some a priori defined (revealed preference) ordering of the observations. Algorithm 1 provides the basis for an alternative ‘best’ test: we can use the algorithm to define the set \( S(p_N, x_N) \), so that we can subsequently check whether \( q_N (x_N) \in S(p_N, x_N) \) (i.e., \( q_N (x_N) \) is SARP consistent) or \( q_N (x_N) \notin S(p_N, x_N) \) (i.e., \( q_N (x_N) \) is SARP inconsistent). It can be verified that this alternative test actually is formally identical to the one of BBC (2003), except from the important difference that it does not require a prior ordering specification - it simultaneously considers all possible (\( T! \)) orderings of the \( T \) observations.

3 Compensating and equivalent variations

In this section, we use the results outlined above to define tightest bounds on compensating and equivalent variations. We first present formal definitions of compensating and equivalent variations. Subsequently, we show how to compute tightest bounds on these welfare measures by using our results of the previous sections.

Suppose the policy maker wants to compare two situations characterized by different price regimes: \( p_O \in \mathbb{R}^J_{++} \) represents original (observed; pre-reform) prices and \( p_N \in \mathbb{R}^J_{++} \) represents new (unobserved; post-reform) prices. Income is the same in the two situations, i.e., \( x_O = x_N \). Let \( e(p,u) \) be the expenditure function that associates minimal expenditure with prices \( p \) and utility \( u \). By construction, rational consumer behaviour implies \( e(p_O, u_O) = e(p_N, u_N) = x_N \) (= \( x_O \)) (where we assume that the total budget is fixed). Then, we get the following definitions.

Definition 6 (compensating and equivalent variations)

(i) Compensating variation \( CV = e(p_N, u_N) - e(p_N, u_O) = x_N - e(p_N, u_O) \).

(ii) Equivalent variation \( EV = e(p_O, u_N) - e(p_O, u_O) = e(p_O, u_N) - x_N \).

Tightest bounds for \( CV \). To bound \( CV \), we need to define bounds on \( e(p_N, u_O) \). To do so, we can use the bounds on the cost function established by BBC (2003). Specifically, because \( q(p_O, x_N) \) is assumed to be the observed (pre-reform) demand, we can use the bounds for the cost function \( e(q_O, p_N) \) (that gives the minimal cost for obtaining a bundle on the same indifference curve as \( q_O \) at prices \( p_N \) - this function is equivalent to the expenditure function evaluated at the utility level \( u_O \) generated by \( q_O \) and prices \( p_N \)). We can thus use the Algorithms A and B of BBC (2003) to obtain tightest bounds for \( CV \).

Tightest bounds for \( EV \). To bound \( EV \), we need tightest bounds on \( e(p_O, u_N) \). Let \( e^L \) denote the tightest (= ‘highest’) lower bound and \( e^U \) the tightest (= ‘lowest’) upper bound, so that \( e^L \leq e(p_O, u_N) \leq e^U \). The next algorithm computes \( e^L \) and \( e^U \). (In the algorithm, we make use of the vectors \( p_j \in \mathbb{R}^J \) of which all components are zero except for the \( j \)-th component, which equals one.)

Algorithm 2 (computing iterated bounds on \( EV \))

Input: \( \{p_N, x_N\} \) and \( \{p_1, \ldots, p_T; q_1 (x_1), \ldots, q_T (x_T)\} \).

Output: \( e^L \) and \( e^U \).

Step 1: Use Algorithm 1 to compute the most informative incomes \( \hat{x}_1, \ldots, \hat{x}_T \).

Step 2: Set \( W(p_N, x_N) = \emptyset \). For any \( k \in \{0, \ldots, J - 1\} \), take any selection of \( k \) mutually different \( j_1, \ldots, j_k \in \{1, \ldots, T\} \) and any selection of \( J - 1 - k \) mutually different \( j_{k+1}, \ldots, j_{j-1} \in \{1, \ldots, J\} \).

\( ^8 \)BBC (2003) originally introduced a (best) test based on the Generalized Axiom of Revealed Preference (GARP) rather than SARP (which we consider here, following BBC (2008)). However, it is straightforward to adapt their ideas to obtain a best SARP-based test. See, for example, Varian (1982 and 2006) for the subtle difference between SARP and GARP.
If \( \mathbf{p}_N, \mathbf{p}_j, \ldots, \mathbf{p}_k, \mathbf{p}_{j+1}, \ldots, \mathbf{p}_{j-1} \) are \( J \) linear independent vectors, then compute the unique \( \mathbf{q}_N \in \mathbb{R}^J \) that solves \( \mathbf{p}_N^T \mathbf{q}_N = x_N, \mathbf{p}_j^T \mathbf{q}_N = \hat{x}_j, \ldots, \mathbf{p}_k^T \mathbf{q}_N = \hat{x}_k, \mathbf{p}_{j+1}^T \mathbf{q}_N = 0, \ldots, \mathbf{p}_{j-1}^T \mathbf{q}_N = 0 \) and add \( \mathbf{q}_N \) to \( W(\mathbf{p}_N, x_N) \). Else take another selection or go to the next \( k \).

**Step 3:** Set \( V(\mathbf{p}_N, x_N) = \emptyset \). Compute \( V(\mathbf{p}_N, x_N) = W(\mathbf{p}_N, x_N) \cap S(\mathbf{p}_N, x_N) \).

**Step 4:** For any \( \mathbf{q} \in V(\mathbf{p}_N, x_N) \), use Algorithm A (resp. Algorithm B) of BBC (2003) to compute \( e_{\mathbf{q}}^L \) (resp. \( e_{\mathbf{q}}^U \)).

**Step 5:** Set \( e^L = \min_{\mathbf{q} \in V(\mathbf{p}_N, x_N)} e^L_{\mathbf{q}} \) and \( e^U = \max_{\mathbf{q} \in V(\mathbf{p}_N, x_N)} e^U_{\mathbf{q}} \).

This algorithm is very easy-to-implement and will efficiently compute \( e^L \) and \( e^U \). More precisely, we can refer to our discussion on the efficiency of Algorithm 1 in the previous section, which carries over to BBC (2003)'s Algorithms A and B (which are formally similar to Algorithm 1). Next, Proposition 2 implies that the closure of \( S(\mathbf{p}_N, x_N) \) is a convex set defined by linear constraints. Steps 2 and 3 of Algorithm 2 then compute the extreme points (or vertices) of this convex set. Essentially, defining each extreme point boils down to finding the unique solution of a system with \( J \) linear constraints that follow from the characterization of the convex set. That is, the budget constraint (i.e. \( \mathbf{p}_N^T \mathbf{q}_N = x_N \)), the constraints corresponding to a selection of \( k \) observations (i.e. \( \mathbf{p}_j^T \mathbf{q}_N = \hat{x}_j, \ldots, \mathbf{p}_k^T \mathbf{q}_N = \hat{x}_k \)) and \( J - 1 - k \) positivity constraints (i.e. \( \mathbf{p}_{j+1}^T \mathbf{q}_N = 0, \ldots, \mathbf{p}_{j-1}^T \mathbf{q}_N = 0 \)).

Some of the solutions of Step 2 do not necessarily belong to the support set \( S(\mathbf{p}_N, x_N) \), which is why we need the additional Step 3 to obtain only the relevant points (i.e. the extreme points). Finally, by construction the set \( V(\mathbf{p}_N, x_N) \) is finite and discrete, which implies that Step 4 of Algorithm 2 is computable in finite time.

Example 2 illustrates the different steps of Algorithm 2. The following lemma formally states that the algorithm effectively compute the tightest bounds on EV.

**Lemma 2 (iterated bounds are tightest)** The values \( e^L \) and \( e^U \) produced by Algorithm 2 define tightest bounds on EV.

**Example 2** Figure 1 graphically illustrates the intuition behind Algorithm 2. For simplicity, we focus on a setting with only two goods and three observed price vectors (i.e. three expansion paths). The upper-left panel of the figure shows the support set \( S(\mathbf{p}_N, x_N) \), which corresponds to the bold line segment. The set \( S(\mathbf{p}_N, x_N) \) is characterized by the most informative incomes \( \hat{x}_1, \hat{x}_2 \) and \( \hat{x}_3 \), which are obtained through Step 1 of Algorithm 2. The corresponding set of extreme points \( V(\mathbf{p}_N, x_N) = \{ \mathbf{q}_{N1}, \mathbf{q}_{N2} \} \); this set is constructed in Steps 2 and 3 of Algorithm 2. The upper-right and lower-left panels of Figure 1 then show the inner and outer bounds for the indifference curves associated with, respectively, \( \mathbf{q}_{N1} \) and \( \mathbf{q}_{N2} \). In turn, this defines the lower bounds \( e^L_{\mathbf{q}_{N1}} \) and \( e^L_{\mathbf{q}_{N2}} \) and the upper bounds \( e^U_{\mathbf{q}_{N1}} \) and \( e^U_{\mathbf{q}_{N2}} \), which are generated in Step 4 of Algorithm 2. Finally, the lower-right panel of Figure 1 shows the resulting values of \( e^L \) and \( e^U \), which are obtained in Step 5 of Algorithm 2. Here, we have \( e^L = \min \{ e^L_{\mathbf{q}_{N1}}, e^L_{\mathbf{q}_{N2}} \} = e^L_{\mathbf{q}_{N1}} = e^L_{\mathbf{q}_{N2}} \) and \( e^U = \max \{ e^U_{\mathbf{q}_{N1}}, e^U_{\mathbf{q}_{N2}} \} = e^U_{\mathbf{q}_{N1}} \).

---

9 Although Step 2 is directly implementable, we also note that it should not be the most efficient way to compute the extreme points of our convex set. Indeed, given that this set is characterized by linear constraints, computing these extreme points is equivalent to finding all basic feasible solutions of a system of linear equations. Alternative algorithms for computing these basic feasible solutions are available in the Operations Research literature.

10 Since there are only two goods in this example, the support set \( S(\mathbf{p}_N, x_N) \) actually coincides with BBC's support set \( S^{B/B} (\mathbf{p}_N, x_N) \), which are characterized by intersection demands (see Proposition 1). (Correspondingly, the most informative incomes \( \hat{x}_1, \hat{x}_2 \) and \( \hat{x}_3 \) equal the intersection incomes \( \hat{x}_1, \hat{x}_2 \) and \( \hat{x}_3 \).) As explained above, the sets \( S(\mathbf{p}_N, x_N) \) and \( S^{B/B} (\mathbf{p}_N, x_N) \) need not coincide in case there are more than two goods. We choose to focus on a two-goods setting here as this allows us to better illustrate the mechanics of Algorithm 2.

11 These bounds for indifference curves are (implicitly) constructed in Algorithms A and B of BBC (2003). We refer to these authors for a detailed discussion on the construction method. See in particular their Figure 7.
Figure 1: Illustration of Algorithm 2
4 Conclusion

In this paper we have complemented and generalized the results of Blundell, Browning and Crawford (2003, 2008). We defined tightest “iterated” (nonparametric) bounds on Marshallian demands that apply to any number of goods. These bounds are sharp under the strong axiom of revealed preference, SARP. We were thus able to show they provide sharp bounds for welfare measures.

We have established a complete toolkit for a powerful nonparametric welfare analysis based on Hicksian compensating and equivalent variations. We show that our iterated bounds method involves computational algorithms that are easily implemented.

Appendix

Proof of Proposition 1

By construction we have \( q_N \in P^t(\hat{x}_t) \) for any \( q_N \in B(p_N, x_N) \). If \( q_N \in S_B(p_N, x_N) \) and \( q_N \neq q_t(\hat{x}_t) \) for all \( t \), then SARP consistency for \( q_N R^t(q_t(\hat{x}_t)) \) implies that \( p_t(q_t(\hat{x}_t)) < p_t(q_N) \) (i.e. not \( q_t(\hat{x}_t) R^t(q_N) \)).

Next, if \( q_N = q_t(\hat{x}_s) \in S_B(p_N, x_N) \) for some \( s \), then SARP consistency requires the same for all observations \( t \neq s \).

Conversely, take any \( q_N \in B(p_N, x_N) \), then \( p_t(q_t(\hat{x}_t)) < p_t(q_N) \) for all \( t \) (i.e. condition (i) holds) excludes \( q_t(\hat{x}_t) R q_N \). So a rejection of SARP requires \( q_N R q_t(\hat{x}_t) \) and \( p_t(q_t(\hat{x}_t)) \geq p_t(q_N) \) (i.e. \( q_t(\hat{x}_t) R^t q_N \)). But this last inequality is excluded by assumption, and thus \( q_N \in S_B(p_N, x_N) \). A similar reasoning holds for \( q_N = q_t(\hat{x}_s) \) (i.e. if condition (ii) holds).

Proof of Proposition 2

Suppose \( q_N \in S(p_N, x_N) \) and \( q_N \neq q_t(\hat{x}_t) \) for all \( t \). By construction we have that \( q_N R q_t(\hat{x}_t) \) for any \( q_N \in B(p_N, x_N) \). So SARP consistency requires that \( p_t(q_t(\hat{x}_t)) < p_t(q_N) \). Next, assume that \( q_N = q_t(\hat{x}_s) \in S(p_N, x_N) \) for some \( s \). Then, SARP consistency requires the same for all \( t \neq s \).

Conversely, take any \( q_N \in B(p_N, x_N) \) and suppose that \( p_t(q_t(\hat{x}_t)) < p_t(q_N) \) for all \( t \) (i.e. condition (i) holds). Then, normality implies for all \( x_t \leq \tilde{x}_t \) that \( p_t(q_t(x_t)) \leq p_t(q_t(\hat{x}_t)) < p_t(q_N) \). Therefore, by Definition 5 and the above, we cannot have \( q_t(x_t) R q_N \). As such, there can be a rejection of SARP only if, for some income \( x_t \), we have \( q_N R q_t(x_t) \) and \( p_t(q_t(x_t)) \geq p_t(q_N) \). Suppose, then, that we do have such a rejection, i.e. there exists an income \( x_t \) for which \( q_N R q_t(x_t) \) and \( p_t(q_t(x_t)) \geq p_t(q_N) \). Since \( p_t(q_t(\hat{x}_t)) < p_t(q_N) \), normality implies that \( x_t > \tilde{x}_t \). This gives us the wanted contradiction, since Definition 5 and the above then exclude \( q_N R q_t(x_t) \).

A similar reasoning holds for \( q_N = q_t(\hat{x}_s) \) (i.e. condition (ii) holds), which finishes the proof.

Proof of Lemma 1

Algorithm 1 is similar to Algorithm B of BBC (2003). Given this, we can straightforwardly adapt the proof of these authors’ Proposition 3 to obtain the result stated in Lemma 1.

Proof of Lemma 2

To bound EV and thus \( \epsilon(p_o, u_N) \), we need to find, for any \( q_N \in S(p_N, x_N) \), the nonparametrically constructed ‘revealed-preferred’ set \( RP(q_N) \), which contains all bundles to which \( q_N \) is preferred to, and the ‘not-revealed-worse’ set \( NRW(q_N) \), which contains all bundles that are not revealed worse to \( q_N \). (See Varian (1982) for an extensive discussion of the sets \( RP(q_N) \) and \( NRW(q_N) \).

Given our results in Section 2, we can define tightest bounds on EV by computing \( e_{q_N}^L \) (resp. \( e_{q_N}^U \)) for any \( q_N \in S(p_N, x_N) \). Now, Proposition 2 implies that the closure of \( S(p_N, x_N) \) is a convex set and, as discussed in the main text, \( V(p_N, x_N) \) contains all the extreme points of this convex set. As such, we get that any \( q_N \in S(p_N, x_N) \) can be written as a convex combination of elements of \( V(p_N, x_N) \), i.e. \( q_N = \sum_k \lambda_k q_k \) (with \( \lambda_k > 0 \) and \( \sum_k \lambda_k = 1 \)) for \( q_k \in V(p_N, x_N) \).
Given this, and using convexity of preferences (represented by the sets $RP(q_N)$ and $NRW(q_N)$), we get $RP(q_N) \subseteq RP(q_k)$ for at least one $q_k \in V(p_N, x_N)$ and also that $NRW(q_N) \subseteq NRW(q_k)$ for at least one, possibly different, $q_k \in V(p_N, x_N)$. As such, in order to nonparametrically identify the lower bound $e^L$ (respectively, upper bound $e^U$), we need to take the minimum (respectively, maximum) of the lower (respectively, upper) bounds over all the elements of $V(p_N, x_N)$, i.e. $e^L = \min_{q_N \in V(p_N, x_N)} e^L_{q_N}$ and $e^U = \max_{q_N \in V(p_N, x_N)} e^U_{q_N}$.
