Sound Enhances Visual Perception: Cross-Modal Effects of Auditory Organization on Vision

Jean Vroomen and Beatrice de Gelder
Tilburg University

Six experiments demonstrated cross-modal influences from the auditory modality on the visual modality at an early level of perceptual organization. Participants had to detect a visual target in a rapidly changing sequence of visual distractors. A high tone embedded in a sequence of low tones improved detection of a synchronously presented visual target (Experiment 1), but the effect disappeared when the high tone was presented before the target (Experiment 2). Rhythmically based or order-based anticipation was unlikely to account for the effect because the improvement was unaffected by whether there was jitter (Experiment 3) or a random number of distractors between successive targets (Experiment 4). The facilitatory effect was greatly reduced when the tone was less abrupt and part of a melody (Experiments 5 and 6). These results show that perceptual organization in the auditory modality can have an effect on perceptibility in the visual modality.

Information arriving at the sense organs must be parsed into objects and events. In vision, scene analysis or object segregation succeeds despite partial occlusion of one object by another, shadows that extend across object boundaries, and deformations of the retinal image produced by moving objects. Vision, though, is not the only modality in which object segregation occurs. Auditory object segregation has also been demonstrated (Bregman, 1990). It occurs, for instance, when a sequence of alternating high- and low-frequency tones is played at a certain rate. When the frequency difference between the tones is small, or when they are played at a slow rate, listeners are able to follow the entire sequence of tones, but at bigger frequency differences or higher rates, the sequence splits into two streams, one high and one low in pitch. Although it is possible to shift attention between the two streams, it is difficult to report the order of the tones in the entire sequence. Auditory stream segregation appears to follow, like apparent motion in vision, Korte's third law (Korte, 1915): When the distance in frequency between the tones increases, stream segregation occurs at longer stimulus onset asynchronies (SOAs).

Bregman (1990) described a number of Gestalt principles for auditory scene analysis in which he stressed the resemblance between audition and vision, because principles of perceptual organization—such as similarity (in volume, timbre, and spatial location), good continuation, and common fate—seem to play a similar role in the two modalities. Such a correspondence between visual and auditory organization principles raises an interesting question: Can the perceptual system utilize information from one sensory modality to organize the perceptual array in the other modality? Or, in other words, is scene analysis a cross-modal phenomenon?

There are, of course, well-known examples of cross-modal influences in which one may assume that the perceptual system indeed attributes information from different sensory modalities to a unitary event. There is a whole literature showing that arbitrary combinations of intermodal stimulus features tend to heighten perceptual awareness and lower reaction time compared with unimodal presentation of those features (e.g., Hershenson, 1962; Nickerson, 1973; Posner, Nissen, & Klein, 1976; Simon & Craft, 1970). Cross-modal combinations of features not only enhance stimulus processing but can also change the percept. The prime example is the McGurk effect (McGurk & MacDonald, 1976), in which disreputable speech information from sound and vision is presented. When listeners hear "baba" and at the same time see a speaker articulating "gaga," they tend to combine the information from the two sources into "dada." Cross-modal interactions in the spatial domain have also been found. For example, synchronized sounds and light flashes with a different spatial location tend to be localized closer together (the ventriloquist effect). The common finding is that there is a substantial effect of the light flashes on the location of the sound (e.g., Vroomen, 1999; Vroomen, Bertelson, & de Gelder, 1998), but under the right conditions, one can also observe that the sound attracts the location of the light (Bertelson & Radeau, 1981). The spatial attraction thus occurs both ways and is rather independent of where endogenous or exogenous spatial attention is located (Bertelson, Vroomen, de Gelder, & Driver, 2000; Vroomen, Bertelson, & de Gelder, 2000). Cross-modal interactions have also been observed in the perception of emotions. Listeners having to judge the emotion in the voice are influenced by whether a face expresses the same emotion or a different one, and the converse effect, in which listeners have to judge a face while hearing a congruent or incongruent voice, has also been shown to occur (de Gelder & Vroomen, 2000; Massaro & Egan, 1996).

Massaro (1997) described an influential model accounting for a wide variety of such intersensory effects. The input to the so-called fuzzy logical model of perception (FLMP) consists of modality-specific features (e.g., a rising second formant and lip closure for /ba/; increased pitch level and inflected mouth corners for hap-
Influence, not a direct perceptual link between audition and vision. An intriguing question, though, is whether cross-modal interactions can occur at a more primitive level of perception, a level at which features do not yet exist. Animal studies have provided intriguing neurophysiological evidence indicating that cross-modal interactions can take place at very early stages of sensory processing. Probably one of the best known sites of multimodal convergence and integration is the superior colliculus, a midbrain structure known to play a fundamental role in attentive and orientation behavior (see Stein & Meredith, 1993, for review). In humans as well, neurophysiological evidence of very early cross-modal interactions has been found. For example, Giard and Peronnet (1999) found that tones synchronized with a visual stimulus can generate new neural activities in visual areas as early as 40 ms after stimulus onset and that a visual stimulus can modulate the typical N1 auditory waveform in the primary auditory cortex at around 90–110 ms. Another example of an early interaction between vision and audition is that an angry face combined with a sad voice can modulate, at 178 ms, the electric brain response typical for auditory mismatch negativity (the MMN; de Gelder, Böcker, Tuomainen, Hensen, & Vroomen, 1999).

Given that these cross-modal electrophysiological effects arise very early in time, it seems at least possible that intersensory interactions can occur at primitive levels of perceptual organization. There is, to our knowledge, only one behavioral study showing that, at the level of scene analysis, perceptual segmentation in one modality can influence the concomitant segmentation in another modality. O'Leary and Rhodes (1984) used a display of six dots, three high and three low. The dots were displayed one by one, alternating between the high and low positions and moving from left to right. At slow rates, a single dot appeared to move up and down, whereas at faster rates, two dots were moving horizontally, one above the other. A sequence that was perceived as two dots caused a concurrent auditory sequence to be perceived as two tones as well, at a rate that would yield a single perceptual object when the accompanying visual sequence was perceived as a single object. The number of objects seen thus influenced the number of objects heard, and O'Leary and Rhodes also found the opposite influence from audition to vision.

At first sight, this seems to be an example of a cross-modal influence on perceptual organization. However, at this stage it is not clear whether the cross-modal effect was truly perceptual or whether it occurred because participants deliberately changed the interpretation about the sounds and dots. It is well known that there is a broad range of rates or tones at which listeners can hear, at will, one or two streams (van Noorden, 1975). O'Leary and Rhodes (1984) presented ambiguous sequences, and it may therefore be the case that a cross-modal influence was found because perceivers changed their interpretation about the sounds and dots although the perception may have been the same. For example, participants having the impression of hearing two streams instead of one may infer that vision should also be two streams instead of one. A voluntary decision would then account for the cross-modal influence, not a direct perceptual link between audition and vision.

In the present study, we pursued this question and investigated a phenomenon that, to the best of our knowledge, has so far not been reported in the literature. It is an illusion that occurs when an abrupt sound is presented during a rapidly changing visual display. Phenomenally, it looks as if the sound is pinning the visual stimulus for a short moment so that the visual display “freezes.” In the present study, we explored this freezing phenomenon. We first tried to determine whether the freezing of the display was a perceptually genuine effect. Previously, Stein, London, Wilkinson, and Price (1996) had shown that a sound can enhance the perceived visual intensity of a stimulus. This enhancement seems to be a close analogue of the freezing phenomenon we observed. However, Stein et al. used a rather artificial and indirect measure of visual intensity (a visual analogue scale in which participants judged the intensity of a light by rotating a dial), and they could not find an enhancement by a sound when the visual stimulus was presented subthreshold. It is therefore unclear whether their effect is truly perceptual rather than postperceptual.

In our experiments, we tried to avoid this difficulty by using a more direct estimate of visual persistence by simply measuring maximum speeded performance on a detection task. Participants saw a four-by-four matrix of flickering dots that was created by rapidly presenting four different displays, each containing four dots in quasi-random positions (see Figure 1). Each display on its own was difficult to see, because it was shown only briefly and immediately followed by a mask. One of the four displays contained a target to be detected. The target consisted of four dots that made up a diamond, and it could appear in the upper left, upper right, lower left, or lower right corner of the matrix. The task of the participants was to detect the position of the diamond as fast and as accurately as possible. In Experiment 1, we investigated whether the detectability of the target could be improved by an abrupt sound presented together with the target. Participants in the experimental condition heard at the target display a high tone, but at the other four-dot displays (the distractors) they heard a low tone. In the control condition, participants heard only low tones. The idea was that the high tone in the sequence of tones would be likely to segregate from the low tones and that under these circumstances, it would increase the detectability of the target display.

**Experiment 1**

**Method.**

**Participants.** Sixteen participants, all first-year students from Tilburg University, received course credits for their participation. They all had normal or corrected-to-normal vision.

**Stimuli.** The visual display was a 4 x 4 matrix of quasi-randomly flickering small white dots presented on the dark background of a 15-in. (38.1-cm) computer screen (Olivetti DSM 60-510). The matrix measured 4.2 by 4.2 cm and was viewed from a distance of 55 cm. The size of each of the dots was 4 x 4 pixels. The flicker of the matrix was created by displaying four different displays successively at a high speed. Each display showed four unique dots of the matrix. When overlaid, the displays would make up the complete matrix. The third of the four-dot displays contained the to-be-detected diamond, in either the upper left, upper right, lower left, or lower right corner of the matrix. Each four-dot display was shown for 97 ms (or 7 refresh cycles on a screen with a vertical retrace of 72 Hz) and was immediately followed by a mask that consisted of the full 4 x 4 matrix of dots. The duration of the mask was also 97 ms, and it was followed by a dark screen for 60 ms, after which the next display was
It is well-known that auditory segregation requires time to build up (Bregman, 1990). Initially, participants are able to already have imposed an auditory organization on the tones. Followed by a blank screen for 60 ms). The warm-up sequences were then displayed. These warm-up sequences were presented together of four tones (LLLL or LLHL) was played before the actual four-dot displays were shown. The target display (in this example the diamond in the upper left corner) was presented at t3. The sequence of the four four-dot displays was repeated without interruption until a response was given. Tones (97 ms in duration) were synchronized with the onset of the four-dot displays. Also not shown in the figure is that from four to eight tone sequences were presented before the four-dot displays were seen. During this warm-up period, tones were synchronized with the mask (presented for 194 ms) followed by the blank screen (60 ms). Participants thus already had heard the sequence of tones several times before the four-dot displays were shown.

Participants heard either a sequence of four low (L) tones of 1000 Hz (denoted as LLLL) or an LLHL sequence in which the H was a high tone 4 ms every 1,016 ms. The sequence was repeated continuously with no interruption until a response was given or until a maximum of 10 cycles was reached.

Participants were told about the two possible sound sequences (LLLL or LLHL), and they were also told that the high tone was synchronized with the target display.

Figure 1. A simplified representation of a stimulus sequence. Big squares represent the dots shown at time t; small squares were actually not seen but are there only to show the position of the dots within the matrix. The four-dot displays were shown for 97 ms each. Not shown in the figure is that each display was immediately followed by a mask (the full matrix of 16 dots) for 97 ms and then a dark blank screen for 60 ms. The target display (in this example the diamond in the upper left corner) was presented at t3. The sequence of the four four-dot displays was repeated without interruption until a response was given. Tones (97 ms in duration) were synchronized with the onset of the four-dot displays. Also not shown in the figure is that from four to eight tone sequences were presented before the four-dot displays were seen. During this warm-up period, tones were synchronized with the mask (presented for 194 ms) followed by the blank screen (60 ms). Participants thus already had heard the sequence of tones several times before the four-dot displays were shown.

Results and Discussion

For each participant and each condition, two response measures were determined: One was the percentage of correct responses, and the other was the number of targets shown (NTS) before a response was made. The NTS was determined for correct responses only, and in all experiments, if the NTS deviated more than ±2 SDs from the individual grand average, it was removed from the analyses. These data were then submitted to an analysis of variance (ANOVA) with sequence of tones (LLLL vs. LLHL) as the within-subjects variable.

All participants performed above chance level (i.e., above 25% with p < .01). The average proportion of correct responses was 55% for the LLLL sequence and 66% for the LLHL sequence, F(1, 15) = 7.84, p < .015. Twelve out of 16 participants performed better with the LLHL sequence, 1 performed at the same level, and 3 participants performed worse (Z = 2.06, p < .025). Not only were participants more correct with the LLHL sequence, but they also required a smaller NTS. The average NTS was 3.32 for the LLLL sequence and 2.86 for the LLHL sequence, F(1, 15) = 4.88, p < .05. Twelve out of 16 participants responded faster with the LLHL sequence, and 4 responded slower. Participants were thus, on average, faster and more accurate when a high tone was presented with the visual target.

One possible interpretation of this result is that the high tone indeed enhanced the visibility of the target display. When participants were asked informally, most of them indeed confirmed that they had experienced the freezing phenomenon described before. On the other hand, another interpretation of our result is that the high tone acted as an attentional cue for when to expect the target display. If a high tone is indeed similar to a cross-modal attentional cue, one would expect other cues that reduce uncertainty about target onset also to enhance performance. In our next experiment we tested for this possibility.

Experiment 2

One possibility is that the high tone in Experiment 1 acted as a warning signal so that participants knew when to expect the target. As an example, it is well-known from the cross-modal attentional cuing literature that an auditory cue that precedes a visual target by between 100 and 300 ms can enhance responding to that visual
target (cf. Spence & Driver, 1997). If attentional cuing is at stake, one would expect that if a high tone precedes the target by one display (i.e., 254 ms), performance should improve because uncertainty about target onset is reduced and because participants are allowed time to prepare for the upcoming target. On the other hand, if the freezing phenomenon is a perceptual phenomenon, one would expect synchrony between tone and visual display to be of critical importance. In that case, one would expect that when a high tone precedes the target and is synchronized with a distractor, it will freeze the distractor display so that performance may even deteriorate.

**Method**

*Participants.* Sixteen new participants drawn from the same population as in Experiment 1 were tested.

*Stimuli and design.* The auditory and visual materials were the same as those in Experiment 1 except that the LLHL sequence was replaced with an LHLL sequence so that the high tone now preceded the target by one display (or 254 ms). The deviating tone thus now accompanied a distractor. Participants were informed about the temporal relation between the high tone and the target, and they were told that they should use the deviant tone as a warning signal of when to expect the target. As before, they were shown, in slow motion, the relation between tone and target. All other aspects of the procedure were the same as those in Experiment 1.

**Results and Discussion**

All participants performed above chance level. The average proportion of correct responses was 55% for the LLLL sequence but only 52% for the LHLL sequence, \( F(1, 15) = 4.36, p = .05 \). Eleven out of 16 participants performed worse with the LHLL sequence, 1 performed at the same level, and 4 performed better (\( Z = 1.54, n.s. \)). Participants required a somewhat smaller NTS for the LHLL sequence, but this effect was not significant. The average NTS was 3.14 for the LLLL sequence and 3.10 for the LHLL sequence (\( F < 1 \)). Seven out of 16 participants required a larger NTS for the LHLL sequence, and 9 participants required a smaller NTS (\( Z = 0.25, n.s. \)).

The results of Experiment 2 thus show that participants made slightly more errors when a high tone preceded the target display. This finding allows us to exclude the possibility that a deviant tone simply acts as a warning signal, because if that were true, one would expect performance to have improved because participants were given prior information about when to expect the target.

As an aside, an interesting observation was that a number of participants remarked that they were able to see the four random dots of the distractor display that was presented with the deviant tone. This was remarkable, because subjectively speaking, this seemed almost impossible when no abrupt sound was heard. This finding is at least suggestive in showing that the freezing phenomenon may occur even when participants are looking for a different display to appear at a different time.

However, so far we have not completely ruled out an attentional explanation. One possibility is that there is rhythmically based anticipation. It may be that the freezing phenomenon is observed only when the target can be anticipated. If that is indeed the case, then jitter between tones should have a disruptive effect.

**Experiment 3**

Experiment 3 was similar to Experiment 1 except that it had an extra condition in which there was jitter between successive tones that disrupted the rhythm of the sequence. If rhythmically based anticipation is at the heart of the freezing phenomenon, jitter should disrupt, or at least attenuate, the facilitatory effect of the high tone.

**Method**

*Participants.* Sixteen new participants were tested.

*Stimuli and design.* The visual materials and the auditory tone sequences were the same as those in Experiment 1. In the no-jitter condition, the SOA between successive tones and four-dot displays was, as before, 254 ms (i.e., 97 ms for the four-dot display, 97 ms for the mask, and 60 ms for the black screen). In the jitter condition, the SOA between successive tones and displays varied randomly from 204 ms to 304 ms in equally likely steps of 25 ms. The visual four-dot displays (97 ms) remained synchronized with the tones and were followed by a mask of the same duration (97 ms), but the duration of the black screen varied between 10 ms and 110 ms depending on SOA. Successive SOAs in the jitter condition were never the same, so rhythmically based anticipation should have been very difficult.

The experiment comprised two blocks (jitter vs. no jitter) of 96 trials each. Within each block, there were 48 trials with the LLHL sequences of tones and 48 trials with the LHLL sequences of tones, 12 for each position of the target. Jitter or no jitter was blocked, and sequence of tones (LLL/L vs. LLHL) was randomized, as before, within a block. Half of the participants started with the jitter condition followed by the no-jitter condition; for the other half, the order was reversed. Before each block was started, participants received 20 practice trials.

**Results and Discussion**

All participants performed above chance level (at \( p < .01 \)). The average percentage of correct responses and the NTS are presented in Table 1. A two-way ANOVA with jitter and sequence of tones as within-subject factors was carried out on the percentage of correct responses and the NTS. In both analyses, there was a main effect of sequence of tones, because target detection with the LHLL sequence of tones was, on average, more correct, \( F(1, 15) = 8.38, p < .02 \), and required a smaller NTS, \( F(1, 15) = 5.32, p < .04 \). The effect of jitter and the interaction between jitter and sequence of tones never even approached significance (all \( F_s < 1 \)).

Experiment 3 thus replicated Experiment 1 in showing that a high tone improved visual target detection. Moreover, the facilitatory effect did not seem to depend on the rhythmic regularity of the tones (or of the visual displays) because there was no hint that jitter disrupted the facilitatory effect. At first sight, this result rules out rhythmically based anticipation as the primary reason for the facilitatory effect. However, two objections against this interpretation can be raised. First, one might argue that the variations in SOA used in the present experiment were not substantial enough. Thus, although rhythmic regularity was disturbed, it might still have been present and caused the facilitatory effect. Second, participants may have anticipated the occurrence of a target by counting the number of distractor displays or tones. Thus far, targets were always followed by three distractor displays. Participants may have counted those displays (or their accompanying tones) and anticipated on the basis of serial order when the target was to appear. If indeed such order-based anticipation is the basis of the freezing phenomenon, then varying the number of distractors should disrupt the effect.

---

1 This possibility was suggested by one of the anonymous reviewers.

Note. In tone sequences, L = low and H = high.

Experiment 4

Experiment 4 was similar to the previous experiment except that instead of jitter, a random number of distractor displays accompanied by low tones was presented between successive targets. The appearance of the target was thus much less predictable than it was when the number of distractors was fixed. If order-based anticipation is to account for the freezing phenomenon, then varying the number of distractors should disrupt the facilitatory effect of the high tone.

Method

Participants. Sixteen new participants were tested.

Stimuli and design. The visual materials and the auditory sequences of tones were the same as those in Experiment 1. In the fixed-distractor condition, there were, as before, three distractor displays between successive targets. In the random-distractor condition, the number of distracter displays and their accompanying low tones varied between successive targets within a single trial from two to six. The number of distractors between successive target displays was thus never the same, so order- and/or rhythmic-based anticipation should have been extremely difficult in this condition.

The experiment comprised two blocks (a fixed number vs. a random number of distractors) of 96 trials each. Within each block, there were 48 trials with the LLLL sequences of tones and 48 trials with the LLHL sequences of tones. 12 for each position of the target. Fixed or random number of distractors was blocked, and sequence of tones (LLLH vs. LLHL) was randomized, as before, within a block. Half of the participants started with the fixed-distractor condition followed by the random-distractor condition; for the other half, the order was reversed. Participants received 20 practice trials before each block.

Results and Discussion

All participants performed above chance level (at $p < .01$). The average percentage of correct responses and the NTS are presented in Table 1. A two-way ANOVA with number of distractors and sequence of tones as within-subjects factors was carried out on the percentage of correct responses and the NTS. In the analysis on accuracy, there was a main effect of sequence of tones, because target detection with the LLHL sequence was, as before, more correct, $F(1, 15) = 10.81, p < .005$. There was no main effect of whether the number of distractors was fixed or varied ($F < 1$), and the interaction between number of distractors and sequence of tones was not significant, $F(1, 15) = 2.33, p = .15$. Inspection of Table 1 suggests that, if anything, the facilitatory effect of the high tone was bigger, not smaller, when the number of distractors varied.

In the analysis of the NTS, no effect was significant (all $F$s < 1). Although there was no effect of NTS, there was certainly no sign of a speed–accuracy trade-off because the average NTS was smaller with a random number of distractors than with a fixed number of distractors.

Experiment 4 thus replicated Experiments 1 and 3 in showing that the high tone improved visual target detection. Moreover, it appeared that the facilitatory effect of the high tone did not hinge on whether or not the target could be anticipated. If anything, the enhancing effect increased when target appearance was unpredictable (potentially because there was more room for improvement). This result therefore rules out order-based anticipation as the main reason for the facilitatory effect.

So far, then, we have shown that a high tone improves detection of a synchronized visual target and that cross-modal attentional cuing is unlikely to account for the effect. However, thus far we have not shown that the effect depends on the auditory organization of the tones. When participants listened to a sequence of LLHL tones, they may have heard either a single stream or two streams, one with low tones and another with a high tone. There has, however, been no experimental demonstration of that, and it may be that whether or not a tone segregates is just epiphenomenal. In fact, it may well be that any tone that is different from other tones, whether it segregates or not, may cause the freezing phenomenon. In the following experiments, we therefore tested whether the auditory organization of the tones was essential.

Experiment 5

An obvious way to prevent segregation is to either increase the duration between successive tones or decrease the frequency difference between the high and low tones. Listeners are then more likely to hear the sequence as a temporally coherent one. However, as shown by van Noorden (1975), listeners can, at will, perceive a sequence either as temporally coherent or as what he called fission. Fission, but not temporal coherence, can be heard quite easily, no matter what the size of the tone interval is. Listeners can thus quite easily segregate a high tone from a low tone, even when the difference between the tones is quite small. We therefore refrained from the obvious possibility of changing the duration or frequency difference between the tones, because participants may segregate the tones anyway in order to maximize performance on the task.

Instead, we presented participants with an LMHL sequence, in which M stands for a middle tone with a 2-ST difference from the low tone. There are two reasons why segregation of the high tone is less likely to occur in the LMHL sequence than in the LLHL sequence. The first is that the high tone is less abrupt in the LMHL sequence than in the LLHL sequence, and it is well-known that abrupt sounds segregate more easily than less abrupt sounds (Bregman, 1990). The second reason why the high tone is unlikely to segregate in the LMHL sequence is that we told participants that the LMHL sequence was the beginning of the tune “Frère Jacques.” The notion was that when listeners perceived this sequence as a melody, the high tone would be unlikely to segregate because it would be captured as an indispensable part of the melody. For these reasons, we expected less segregation of the high tone in the LMHL sequence than in the LLHL sequence. The crucial advantage of this procedure is that the high tone was the
same sound in both sequences of tones. Thus, at the time the visual target was shown, exactly the same stimuli were heard and seen. The only difference between conditions was the tone preceding the high tone. If segregation is critical for the facilitatory effect, one would expect target detection to be more difficult in the LMHL sequence than in the LLHL sequence. On the other hand, if the sequential organization of the tones it not important, it should not matter whether or not the high tone is part of a melody.

**Results and Discussion**

All participants performed above chance level. The average proportion of correct responses was 52% with the "Frère-Jacques" tune and 62% with the LLHL sequence, \( F(1, 15) = 11.49, p < .005 \). Fourteen out of 16 participants performed better with the LLHL sequence, and 2 performed at the same level (\( Z = 3.47, p < .005 \)). Participants not only were more correct but also required a smaller NTS with the LLHL sequence. The average NTS was 2.63 with the "Frère-Jacques" tune and 2.46 with the LLHL sequences, \( F(1, 15) = 13.24, p < .002 \). Twelve out of 16 participants required a smaller NTS with the LLHL sequence than with the "Frère Jacques" tune; 3 participants required a larger NTS, and 1 participant required equal numbers of targets shown (\( Z = 2.06, p < .025 \)).

These results thus show that the perceptual organization of the sequence of tones plays a critical role. The task was much harder when the high tone was heard as part of a melody than when it was not heard as part of a melody. These results therefore show that the auditory organization of the sequence of tones is indeed of importance for observing the freezing phenomenon. In Experiment 6 we explored this phenomenon further.

**Experiment 6**

The results of Experiment 5 are crucial for the interpretation of the freezing phenomenon. The LLHL sequence made visual target detection more difficult because, we reasoned, it made segregation of the high tone unlikely. Segregation was unlikely to occur for two reasons: One was that the high tone in the LMHL sequence, compared with the high tone in the LLHL sequence, was less abrupt; the other was that the LMHL sequence was a tune. A potential problem with the tune explanation is that one runs the risk that participants, when told that they will hear a tune, will actually perform two tasks at the same time: trying to hear the sequence as a tune and to detect the visual target. Trying to hear the sequence as a tune may then interfere with target detection because it requires a certain amount of limited processing resources.

To investigate whether trying to hear the sequence as a tune might be a potential difficulty, we replicated Experiment 5 but varied the instructions. In one condition, we stressed, as before, that the LMHL sequence was the beginning of the tune "Frère-Jacques." But in the other condition, we refrained from making any reference to the "tuneness" of the LMHL sequence. If the instructions caused the difference between the perception of the sequences of tones, then the difference should disappear, or at least attenuate, when no mention of the "tuneness" of the LMHL sequence is made. On the other hand, if the abruptness of the high tone is crucial, then instructions should have no effect.

Moreover, we explored a range of stimulus parameters under which the facilitatory effect of the high tone could be observed. To do so, we varied the display times of the dots and the mask. One may expect performance to improve when the display time of the target is increased and the display time of the mask is decreased. The question of interest is whether the facilitatory effect of the high tone critically depends on task difficulty.

**Method**

Participants. Two groups of 16 students each were tested. One group received the same instructions as in Experiment 5, in which the LMHL sequence was introduced as the beginning of the tune "Frère Jacques." In the other group, no reference to the tune was ever made.

Stimuli and design. Participants heard, as in Experiment 5, an LLHL or an LMHL ("Frère Jacques") sequence of tones. These sequences were combined with three possible combinations of four-dot and mask display times: a 97-ms four-dot display time and a 97-ms mask display time, as used in all previous experiments; an 83-ms four-dot display and a 111-ms mask; and a 111-ms four-dot display and an 83-ms mask. For each display time and sequence of tones, there were eight trials for each of the four positions of the diamond. The whole experiment therefore consisted of 192 experimental trials: 96 for the LLHL sequence and 96 for the LLHL sequence. The trials were randomly mixed, and within a block of 48 consecutive trials, each of the 24 different trials appeared twice. There was a short pause half way. Before actual testing began, a short practice session was given.

**Results and Discussion**

The average proportion of correct responses and the NTS are presented in Table 2. As before, performance was better with the LLHL sequence of tones than with the LMHL sequence. Instructions and the different target and mask display time combinations had no effect on this main effect of the sequences of tones. A three-way mixed ANOVA with instruction as a between-subjects variable and display time and sequence of tones as within-subject variables was carried out on the percentage of correct responses and the NTS. In the analysis on accuracy, there was no overall difference between the groups that received the different instructions \( F < 1 \). As expected, there was a main effect of display time, \( F(2, 60) = 83.53, p < .001 \), because performance improved when targets were displayed for a longer duration. There was also a main effect of sequence of tones, \( F(1, 30) = 13.10, p < .001 \), because performance was better with the LLHL sequence than with the LMHL sequence of tones. All other effects were nonsignificant. Thus, and most important, instructions did not change the difference between LLHL and LMHL sequences of tones, as indicated by a nonsignificant interaction between instruc-
tion and sequence of tones ($F < 1$). Moreover, the interaction between display time and sequence of tones, $F(2, 60) = 2.18$, $p = .12$, and the second-order interaction between instruction, display times, and sequence of tones, $F(2, 60) = 1.10$, $p = .31$, were nonsignificant.

The same pattern was found in the corresponding ANOVA on the NTS. The effect of display time was significant, indicating that participants required a smaller NTS when targets were shown for a longer duration, $F(2, 60) = 13.15$, $p < .001$. The effect of sequence of tones was significant, $F(1, 30) = 7.37$, $p < .01$, because fewer targets were seen when the LLHL sequence was heard than when the LMHL sequence of tones was heard, and all other effects were nonsignificant (all $F$s < 1).

The present results replicate and extend those of Experiment 5. As before, target detection was more difficult when the high tone was part of the LMHL sequence. Whether or not the instructions specified that the LMHL sequence was the beginning of "Frère Jacques" had no effect on this result. Varying the overall difficulty of the task also had no effect. These findings suggest that the abruptness of the high tone, rather than the "tuneness" of the LMHL sequence, is crucial for the improvement in the detectability of the target.

General Discussion

In the present study we demonstrated a new cross-modal phenomenon: The detectability of a visual stimulus is modulated by a synchronously presented abrupt tone. This so-called "freezing" phenomenon was closely related to the perceptual organization of the tone in the auditory modality: The effect was observed when the tone could easily segregate from a sequence of tones, but the effect was greatly attenuated (or it even disappeared) when the same tone was less abrupt or was part of a melody. The phenomenon is unlikely to be accounted for by cross-modal attentional cuing because the effect disappeared when the abrupt sound preceded the target by an SOA at which one might expect a cross-modal attentional cuing effect, and it was unaffected by whether or not the onset of the target was predictable. Because our method allowed us to obtain a direct measure of visibility, these results strongly suggest that the freezing phenomenon is a perceptually genuine effect.

Our findings are similar to the results of Stein, London, Wilkinson, and Price (1996), who reported that a sound can enhance the perceived visual intensity of a stimulus. Our study extends this observation because we used a different measure that relied on maximum speeded performance instead of subjective judgment. Moreover, we showed that the phenomenon was closely related to the perceptual organization of the sound in a sequence of tones. Consequently, we would predict that the results of Stein et al. can be modulated by the perceptual organization of the sound that is synchronized with the visual display.

Our results are also in line with those of O'Leary and Rhodes (1984), who reported that the perceptual organization of tones could influence the perceptual organization of moving dots. They found that when a sequence of high and low tones was heard as two streams, a dot that moved up and down was more likely to be seen as two streams of dots moving horizontally. Other examples of this cross-modal principle were recently demonstrated by Sekuler, Sekuler, and Lau (1997). They found that two disks moving toward one another, coinciding, and then moving apart were perceived as bouncing when a sound was presented at the point of visual coincidence. When there was no sound, it appeared as if the disks continued in their original direction. Our results show that these cross-modal correspondences in perceptual organization have other profound consequences: Namely, a tone that segregates from an auditory stream can segregate a synchronized visual stimulus from a visual stream.

At present, there is a wide variety of neurophysiological findings that show interactions between vision and audition in several cortical and subcortical areas. In humans, several studies have found neural sites of multisensory convergence. In participants making color–word associations, a positron emission tomography study identified several cortical areas of interaction in the parieto-occipital junction and in the right prefrontal cortex (Paulesu et al., 1995). Magnetoencephalography recordings have shown audiovisual interactions in the right parieto-temporal area (Sams & Imada, 1997). And with spatiotemporal analysis of event-related poten-
tials, several distinct audiovisual interaction components have been identified in visual areas, auditory cortex, and right fronto-temporal areas (de Gelder et al., 1999; Giard & Peronnet, 1999).

Animal studies have found polymodal cells that may provide a physiological basis for some of those cross-modal effects (Meredith & Stein, 1986). Multisensory neurons have been found in the deep layers of the superior colliculus in the cat, monkey, and rat but also in cortical areas (e.g., Wallace, Meredith, & Stein, 1992). Not only do these cells respond to inputs from several modalities, but they also integrate information from different modalities by increasing the number of impulses in a multiplicative ratio when presented with multimodal inputs (Wallace, Wilkinson, & Stein, 1996).

One may speculate that cross-modal interactions in general, and the freezing phenomenon in particular, are consistent with a perceptual mechanism that makes coherent interpretations about auditory and visual information that originates from a single object or event. From an ecological point of view, it seems valid to assume that multisensory stimulation that covaries in place and time originates from a single object. Perceptual evaluation in one modality may then have consequences in other modalities so that coherence is maintained. A sound that segregates in the auditory modality may for that reason provoke segregation in the visual modality. Ventriloquism is another demonstration of this principle in the sense that discrepant information about the location of synchronized auditory and visual events is integrated into a coherent representation of the world. Future studies could investigate whether the freezing phenomenon can be observed across other modalities than the auditory and visual (e.g., visual–haptic) and whether cross-modal effects can be found from vision on audition. For example, perhaps tone detection can be enhanced when an accompanying visual scene segregates.
