An Analytic Center Cutting Plane Method to Determine Complete Positivity of a Matrix

Riley Badenbroek, Etienne de Klerk

Tilburg University, r.m.badenbroek@tilburguniversity.edu, e.deklerk@tilburguniversity.edu

We propose an analytic center cutting plane method to determine if a matrix is completely positive, and return a cut that separates it from the completely positive cone if not. This was stated as an open (computational) problem by Berman, Dür, and Shaked-Monderer [Electronic Journal of Linear Algebra, 2015]. Our method optimizes over the intersection of a ball and the copositive cone, where membership is determined by solving a mixed-integer linear program suggested by Xia, Vera, and Zuluaga [INFORMS Journal on Computing, 2018]. Thus, our algorithm can, more generally, be used to solve any copositive optimization problem, provided one knows the radius of a ball containing an optimal solution. Numerical experiments show that the number of oracle calls (matrix copositivity checks) for our implementation scales well with the matrix size, growing roughly like $O(d^2)$ for $d \times d$ matrices. The method is implemented in Julia, and available at <https://github.com/rileybadenbroek/CopositiveAnalyticCenter.jl>.

Key words: copositive optimization; analytic center cutting plane method; completely positive matrices

1. Introduction

We define the completely positive cone $\mathcal{CP}^d \subset \mathbb{S}^d$ as

$$\mathcal{CP}^d := \{BB^\top : B \geq 0, B \in \mathbb{R}^{d \times k} \text{ for some } k\},$$

where \mathbb{S}^d denotes the space of real symmetric $d \times d$ matrices. Completely positive matrices play an important role in optimization. For instance, by a theorem of Motzkin and Straus (1965) (see also De Klerk and Pasechnik (2002)), the stability number of a graph can be formulated as an optimization problem with linear objective and linear constraints over the completely positive cone (or its dual cone). A seminal result by Burer (2009) shows that – under mild assumptions – binary quadratic problems can also be reformulated as

optimization problems over the completely positive cone. Other applications build on the work by Kemperman and Skibinsky (1992), who found that

$$\left\{ \int xx^\top d\mu(x) : \mu \text{ is a finite-valued nonnegative measure supported on } \mathbb{R}_+^d \right\} = \mathcal{CP}^d.$$

This equality has spawned a large number of applications in distributionally robust optimization, e.g. Natarajan et al. (2011) and Kong et al. (2013) (see Li et al. (2014) for a survey).

One advantage of these reformulations is that they transform hard problems into linear optimization problems over a proper cone, which allow them to benefit from the (duality) theory of convex optimization. The difficulty in such problems is essentially moved to the conic constraint. It is therefore unsurprising that even testing whether a matrix is completely positive is NP-hard, cf. Dickinson and Gijben (2014). Several approaches to this testing problem exist in the literature.

Jarre and Schmallowsky (2009) propose an augmented primal-dual method that provides a certificate if $C \in \mathcal{CP}^d$ by solving a sequence of second-order cone problems. However, their algorithm converges slowly if C is on the boundary of \mathcal{CP}^d , and the regularization they propose to solve this is computationally expensive.

An obvious way to verify that C is completely positive is to find a factorization $C = BB^\top$ where $B \geq 0$. Several authors have done this for specific matrix structures, see Dickinson and Dür (2012), Bomze (2018), and the references therein. For general matrices, factorization methods have been proposed by Nie (2014), and Sponsel and Dür (2014), but these methods do not perform well on bigger matrices. Groetzner and Dür (2018) develop an alternating projection scheme that does scale well, but is not guaranteed to find a factorization for a given completely positive matrix. The method struggles in particular for matrices near the boundary of the completely positive cone. Another heuristic method based on projection is given by Elser (2017). Sikirić et al. (2020) can find a rational factorization whenever it exists, although the running time is hard to predict.

To actually optimize over the completely positive cone is even harder. Bomze et al. (2011) suggest a factorization heuristic with promising numerical performance. A more naive approach to solving completely positive optimization problems is to replace the cone \mathcal{CP}^d with a tractable outer approximation, such as the cone of doubly nonnegative matrices (i.e. the symmetric positive semidefinite matrices with nonnegative elements). If

the problem over this outer approximation has an optimal solution C , one would not only like to check if $C \in \mathcal{CP}^d$, but also to generate a cut that separates C from \mathcal{CP}^d if $C \notin \mathcal{CP}^d$. After adding the cut to the relaxation, the relaxation may be re-solved, hopefully yielding a better solution (this scheme is mentioned in e.g. Sponsel and Dür (2014) and Berman et al. (2015)).

Burer and Dong (2013) proposed a method to generate such a cut for 5×5 matrices. Sponsel and Dür (2014) suggested an algorithm based on simplicial partition. Nevertheless, finding a cutting plane for the completely positive matrices is still listed as an open problem by Berman et al. (2015).

Our approach will optimize over the dual cone of \mathcal{CP}^d (with respect to the trace inner product $\langle \cdot, \cdot \rangle$), which is known as the copositive cone. This cone is defined as

$$\mathcal{COP}^d := \{X \in \mathbb{S}^d : y^\top X y \geq 0 \text{ for all } y \in \mathbb{R}_+^d\}.$$

It is well known that $C \in \mathcal{CP}^d$ if and only if $\langle C, X \rangle \geq 0$ for all $X \in \mathcal{COP}^d$. Hence, minimizing $\langle C, X \rangle$ over $X \in \mathcal{COP}^d$ should give us an answer to the question if $C \in \mathcal{CP}^d$ or not, and if not, we immediately have an $X \in \mathcal{COP}^d$ that induces a valid cut.

It should be noted that determining if a matrix X lies in \mathcal{COP}^d is co-NP-complete, see Murty and Kabadi (1987). The classical copositivity test is due to Gaddum (1958), but his procedure requires performing a test for all principal minors of a matrix, which does not scale well to larger d . Nie et al. (2018) have proposed an algorithm based on semidefinite programming that terminates in finite time, although the actual computation time is hard to predict. Anstreicher (2020) shows that copositivity can be tested by solving a mixed-integer linear program (MILP), building on work by Dickinson (2019). See Hiriart-Urruty and Seeger (2010) for a review of the properties of copositive matrices.

Our chosen method of testing if a matrix X is copositive is the same as in Badenbroek and de Klerk (2019), which is similar to Anstreicher's. Our method also solves an MILP, and also generates a $y \geq 0$ such that $y^\top X y < 0$ if X is not copositive. The main difference is that our method derives from Xia et al. (2018) instead of Dickinson (2019).

Several approaches to copositive optimization exist in the literature. Bundfuss and Dür (2008, 2009) use polyhedral inner and outer approximations based on simplicial partitions that are refined in regions interesting to the optimization. Hierarchies of inner approximations of the copositive cone are proposed by Parrilo (2000), De Klerk and Pasechnik (2002)

(see also Bomze and De Klerk (2002)) and Peña et al. (2007). Yıldırım (2012) proposes polyhedral outer approximations of the copositive cone, and analyzes the gap to the inner approximations by De Klerk and Pasechnik. Lasserre (2014) proposes a spectrahedral hierarchy of outer approximations of \mathcal{COP}^d . Perhaps most closely related to our work is the cutting-plane approach by Anstreicher et al. (2017), although they do not report computational results for their algorithms, and use a different separation oracle for the copositive cone. Their main analysis concerns an ellipsoid method requiring a polynomial number of iterations, but they also suggest volumetric center and analytic center cutting plane methods as alternatives. They expect those last two methods to outperform the ellipsoid method in practice, and we present evidence in that direction in Section 3.

Our approach to optimize over the copositive cone is to use an analytic center cutting plane method. Therefore, it is convenient to use a simple polyhedral outer approximation of the copositive cone: $\{X \in \mathbb{S}^d : y^\top X y \geq 0 \forall y \in \mathcal{Y}\}$, where $\mathcal{Y} \subset \mathbb{R}_+^d$ is a finite set of vectors. These vectors will be generated by performing the copositivity check for some matrix X , and if it turns out there exists a $y \geq 0$ such that $y^\top X y < 0$, this y is added to \mathcal{Y} .

Analytic center cutting plane methods were first introduced by Goffin and Vial (1993) (see Goffin and Vial (2002) for a survey by the same authors, or Boyd et al. (2011)). The advantage of analytic center cutting plane methods is that the number of iterations scales reasonably with the problem dimension. For instance, Goffin et al. (1996) find that the number of iterations is $O^*(n^2/\epsilon^2)$, where n is the number of variables, ϵ is the desired accuracy, and O^* ignores polylogarithmic terms. In every iteration of our algorithm, the main computational effort is solving an MILP whose size does not change throughout the algorithm's run.

We describe our method in detail Section 2 and conduct numerical experiments in Section 3.

Notation

Throughout this work, we use the Euclidean inner product on \mathbb{R}^n , and the trace inner product $\langle \cdot, \cdot \rangle$ on \mathbb{S}^d . For some vector $x \in \mathbb{R}^n$ with all elements unequal to 0, and some integer $i \in \mathbb{Z}$, let $x^i := \begin{bmatrix} x_1^i & \cdots & x_n^i \end{bmatrix}^\top$.

Since \mathbb{S}^d is isomorphic to $\mathbb{R}^{d(d+1)/2}$, we can also consider our optimization over \mathcal{COP}^d as an optimization over $\mathbb{R}^{d(d+1)/2}$. To do that, we follow the convention from Julia's

`MathOptInterface` package, which (implicitly) uses the following vectorization operator on $X = [X_{ij}] \in \mathbb{S}^d$:

$$\text{svec}(X) := \begin{bmatrix} X_{11} & X_{12} & X_{22} & X_{13} & X_{23} & \cdots & X_{dd} \end{bmatrix}^\top,$$

i.e. $\text{svec}(X)$ contains the upper triangular part of the matrix. Let $\text{smat} : \mathbb{R}^{d(d+1)/2} \rightarrow \mathbb{S}^d$ be the inverse of svec , and let $\text{smat}^* : \mathbb{S}^d \rightarrow \mathbb{R}^{d(d+1)/2}$ be the adjoint of smat .

The problem we will look at for some fixed $C \in \mathbb{S}^d$ is

$$\min_X \{ \langle C, X \rangle : \|\text{svec}(X)\|^2 \leq 1, X \in \mathcal{COP}^d \}. \quad (1)$$

If $X \in \mathcal{COP}^d$ is an optimal solution to (1), then $C \in \mathcal{CP}^d$ if and only if $\langle C, X \rangle \geq 0$.

2. An Analytic Center Cutting Plane Method

Analytic center cutting plane methods can be used to solve optimization problems of the form

$$\inf_x \{ c^\top x : x \in \mathcal{X} \subseteq \mathbb{R}^n \}, \quad (2)$$

where $c \in \mathbb{R}^n$ and \mathcal{X} is a nonempty, bounded, convex set for which we know a separation oracle. In other words, given some point $x \in \mathbb{R}^n$, one should be able to determine if $x \in \mathcal{X}$ or not, and moreover, if $x \notin \mathcal{X}$, we must be able to generate a halfspace \mathcal{H} such that $\mathcal{X} \subseteq \mathcal{H}$ but $x \notin \mathcal{H}$.

The idea behind analytic center cutting plane methods is to maintain a tractable outer approximation of the optimal set of (2). Then, in every iteration k , one approximates the analytic center x_k of this set. One of two things will happen:

- x_k does not lie in \mathcal{X} . In this case, use a separating hyperplane to remove x_k from the outer approximation of the feasible set.
- x_k lies in \mathcal{X} . Since x_k is feasible for (2), any optimal solution must have an objective value that is at least as good as $\langle c, x_k \rangle$. Any optimal solution will therefore lie in the halfspace $\{x \in \mathbb{R}^n : \langle c, x \rangle \leq \langle c, x_k \rangle\}$, and one may thus restrict the outer approximation to this halfspace.

The constraint $\|x\|^2 \leq 1$ from (1) will be included in our outer approximation explicitly. Hence, there are three remaining questions we have to answer before we can solve (1):

1. How will we generate separating hyperplanes for the constraint $\text{smat}(x) \in \mathcal{COP}^d$?
2. How do we compute the analytic center of the outer approximation?

3. How can one prune constraints that do not have a large influence on the location of the analytic center?

These three questions will be answered in Sections 2.1, 2.2, and 2.3, respectively. Then, we state our algorithm in Section 2.4 and make some remarks concerning its complexity in Section 2.5.

2.1. Generating Cuts

The first question we will answer is how to generate separating hyperplanes for the copositive cone. Note that $X \in \mathbb{S}^d$ is copositive if and only if

$$\min_y \{y^\top X y : e^\top y = 1, y \geq 0\}, \quad (3)$$

where e is the all-ones vector, is nonnegative. It was shown by Xia et al. (2018) that the value of (3) is equal to the optimal value of the mixed-integer linear program

$$\left. \begin{array}{ll} \min_{y,z,\mu,\nu} & -\mu \\ \text{subject to} & Xy + \mu e - \nu = 0 \\ & e^\top y = 1 \\ & 0 \leq y_i \leq z_i \quad \forall i = 1, \dots, d \\ & 0 \leq \nu_i \leq 2d(1 - z_i) \max_{k,l} |X_{kl}| \quad \forall i = 1, \dots, d \\ & z_i \in \{0, 1\} \quad \forall i = 1, \dots, d, \end{array} \right\} \quad (4)$$

and that any optimal y from (4) is also an optimal solution for (3). If the optimal value of (4) is nonnegative, then X is copositive. If the optimal value of (4) is negative, then an optimal solution $y \geq 0$ from (4) admits the halfspace $\mathcal{H} = \{X' \in \mathbb{S}^d : y^\top X' y \geq 0\}$ such that $\mathcal{COP}^d \subset \mathcal{H}$ but $X \notin \mathcal{H}$. Note that this method was also used in Badenbroek and de Klerk (2019).

As noted in Section 1, there are alternative methods to test matrix copositivity. The method by Gaddum (1958) is already outperformed by the above method for the 6×6 matrices in our test set, and our MILP method scales considerably better. The method by Nie et al. (2018) can also become too slow for our purposes at moderate matrix dimensions. A recent method by Anstreicher (2020) also solves an MILP, which we expect to perform similar to (4).

In theory, we can therefore determine if a matrix is copositive by solving one MILP. In practice however, a solver may return a solution $(\hat{y}, \hat{z}, \hat{\mu}, \hat{\nu})$ to (4) where $\hat{y}^\top \hat{\nu} > 0$. This is problematic because the variable ν_i in (4) corresponds to the Lagrange multiplier for the constraint $y_i \geq 0$ from (3), and therefore any solution $(\hat{y}, \hat{z}, \hat{\mu}, \hat{\nu})$ to (4) should satisfy $\hat{y}^\top \hat{\nu} = 0$. Due to numerical tolerances, this condition is not always met in practice. A solver may return a solution with $\hat{z} \notin \{0, 1\}^d$, which mostly seems to occur if X has low rank (or is close to a low rank matrix). To find the optimal solution to (4) if this occurs, we fix z to the element-wise rounded value $\text{ROUND}(\hat{z})$ of \hat{z} . If the resulting problem is still feasible, we can compare its complementary solution with the solution to (4) under the additional restriction that $z \in \{0, 1\}^d \setminus \{\text{ROUND}(\hat{z})\}$, and return the best of these two solutions. If the constraint $z = \text{ROUND}(\hat{z})$ does make the problem infeasible, we know that any optimal solution will have $z \in \{0, 1\}^d \setminus \{\text{ROUND}(\hat{z})\}$. The details of this procedure are given in Algorithm 1, where $\text{val}(\mathcal{M})$ denotes the objective value of the optimal solution returned by the solver when solving the model \mathcal{M} .

2.2. Approximating the Analytic Center

Now that we saw how to generate cuts for the copositive cone, we turn our attention to the second question: how to approximate the analytic center of our outer approximation. For the sake of concreteness, let us suppose the convex body \mathcal{Q} for which we want to approximate the analytic center is the intersection of a ball and a polyhedron, i.e.

$$\mathcal{Q} = \{x \in \mathbb{R}^n : \|x\|^2 \leq r^2, a_i^\top x \leq b_i \forall i = 1, \dots, m\}, \quad (5)$$

where $a_1^\top, \dots, a_m^\top$ are the rows of a matrix A , and $b := (b_1, \dots, b_m)$. The analytic center of \mathcal{Q} is the optimal solution x to the problem

$$\inf_x \left\{ -\log(r^2 - \|x\|^2) - \sum_{i=1}^m \log(b_i - a_i^\top x) \right\}. \quad (6)$$

It is well known that self-concordant barrier functions only have an analytic center when their domain is bounded (see e.g. (Renegar 2001, Corollary 2.3.6)). This is why we use the upper bound r on $\|x\|$. Of course, a more traditional solution would be to ensure that the linear constraints $Ax \leq b$ describe a bounded set. We decided against this for reasons of numerical stability (more details in Section 2.5).

Since the objective function in (6) can only be evaluated at x where $\|x\|^2 < r^2$ and $Ax < b$, we will use an infeasible-start Newton method to solve (6). Similar to (Boyd et al.

Algorithm 1 Method for testing copositivity or finding deep cuts

Input: Matrix $X \in \mathbb{S}^d$ which we want to test for copositivity.

```

1: function TESTCOPOSITIVE( $X$ )
2:   Let  $\mathcal{M}$  refer to the model (4) with input  $X$ 
3:    $(\hat{y}, \hat{z}, \hat{\mu}, \hat{\nu}) \leftarrow \text{SOLVEMODEL}(\mathcal{M})$  ▷ See Line 10
4:   if  $\hat{y}^\top X \hat{y} \geq 0$  then
5:     return true ▷ Returns true if  $X$  is copositive
6:   else ▷ Returns a deep cut if  $X$  is not copositive:
7:     return  $\{\hat{X} \in \mathbb{S}^d : \hat{y}^\top \hat{X} \hat{y} \geq 0\}$  ▷ A halfspace  $\mathcal{H}$  such that  $\text{COP}^d \subseteq \mathcal{H}$  but  $X \notin \mathcal{H}$ 
8:   end if
9: end function

10: function SOLVEMODEL( $\mathcal{M}, u = +\infty$ )
11:   Let  $(\hat{y}, \hat{z}, \hat{\mu}, \hat{\nu})$  be the solution to the model  $\mathcal{M}$  returned by the solver
12:   if  $\hat{y}^\top \hat{\nu} > 0$  and  $\text{val}(\mathcal{M}) < u$  then
13:     Let  $\overline{\mathcal{M}}$  be the model  $\mathcal{M}$  with the added constraint  $z = \text{ROUND}(\hat{z})$ 
14:     Let  $\mathcal{M}'$  be the model  $\mathcal{M}$  with the added constraint  $\sum_{i:\text{ROUND}(\hat{z}_i)=0} z_i +$ 
15:        $\sum_{i:\text{ROUND}(\hat{z}_i)=1} (1 - z_i) \geq 1$ 
16:     if  $\overline{\mathcal{M}}$  is feasible then
17:       Compute the optimal solution to  $\overline{\mathcal{M}}$ , and  $\text{SOLVEMODEL}(\mathcal{M}', \text{val}(\overline{\mathcal{M}}))$  if
18:        $\mathcal{M}'$  is feasible
19:       return the solution with the best objective value out of these two
20:     else
21:       return  $\text{SOLVEMODEL}(\mathcal{M}')$ 
22:     end if
23:   else
24:     return the solution  $(\hat{y}, \hat{z}, \hat{\mu}, \hat{\nu})$ 
25:   end if
26: end function

```

2011, Section 2), one can reformulate the problem of computing the analytic center of \mathcal{Q} as

$$\inf_{x,d,s} \left\{ -\log(d) - \sum_{i=1}^m \log(s_i) : d \leq r^2 - \|x\|^2, s \leq b - Ax \right\}, \quad (7)$$

which has Lagrangian

$$L(x, d, s, \kappa, \lambda) = -\log(d) - \sum_{i=1}^m \log(s_i) + \kappa(d - r^2 + \|x\|^2) + \lambda^\top (s - b + Ax),$$

with gradient

$$\nabla L(x, d, s, \kappa, \lambda) = \begin{bmatrix} 2\kappa x + A^\top \lambda \\ -d^{-1} + \kappa \\ -s^{-1} + \lambda \\ d - r^2 + \|x\|^2 \\ s - b + Ax \end{bmatrix}. \quad (8)$$

For the sake of completeness, let us show that it suffices to compute a stationary point of the Lagrangian.

PROPOSITION 1. *Let $A \in \mathbb{R}^{m \times n}$ have rows $a_1^\top, \dots, a_m^\top$, and let $b \in \mathbb{R}^m$, and $r > 0$. Let \mathcal{Q} be as defined in (5), and assume that it has nonempty interior. Then, x_* is the analytic center of \mathcal{Q} if and only if there exist $d_*, s_*, \kappa_*, \lambda_* > 0$ such that $\nabla L(x_*, d_*, s_*, \kappa_*, \lambda_*) = 0$.*

Proof. Because \mathcal{Q} is nonempty and bounded, it has an analytic center, and problem (7) has an optimal solution. Since (7) is convex, a feasible solution (x_*, d_*, s_*) is optimal if and only if it satisfies the KKT conditions: there should exist κ_*, λ_* such that

$$\left\{ \begin{array}{l} \begin{bmatrix} 2\kappa_* x_* + A^\top \lambda_* \\ -d_*^{-1} + \kappa_* \\ -s_*^{-1} + \lambda_* \end{bmatrix} = 0 \\ \kappa_*(d_* - r^2 + \|x_*\|^2) = 0 \\ \lambda_*^\top (s_* - b + Ax_*) = 0 \\ d_* \leq r^2 - \|x_*\|^2 \\ s_* \leq b - Ax_* \\ \kappa_*, \lambda_* \geq 0. \end{array} \right.$$

Since $\kappa_* = d_*^{-1} > 0$ and $\lambda_* = s_*^{-1} > 0$, the claim follows. □

The first order approximation for the Lagrangian shows

$$\nabla L(x + \Delta x, d + \Delta d, s + \Delta s, \kappa + \Delta \kappa, \lambda + \Delta \lambda) \approx \nabla L(x, d, s, \kappa, \lambda) + \nabla^2 L(x, d, s, \kappa, \lambda) \begin{bmatrix} \Delta x \\ \Delta d \\ \Delta s \\ \Delta \kappa \\ \Delta \lambda \end{bmatrix}, \quad (9)$$

which means we can solve a linear system to find the Newton step $(\Delta x, \Delta d, \Delta s, \Delta \kappa, \Delta \lambda)$ with which we can approximate a stationary point of L . Next, we find that

$$\nabla^2 L(x, d, s, \kappa, \lambda) = \begin{bmatrix} 2\kappa I & 0 & 0 & 2x & A^\top \\ 0 & d^{-2} & 0 & 1 & 0 \\ 0 & 0 & \text{Diag}(s^{-2}) & 0 & I \\ 2x^\top & 1 & 0 & 0 & 0 \\ A & 0 & I & 0 & 0 \end{bmatrix}. \quad (10)$$

Thus, if we substitute the expressions (8) and (10) in (9), we see that the Newton step should satisfy

$$0 = \begin{bmatrix} 2\kappa x + A^\top \lambda \\ -d^{-1} + \kappa \\ -s^{-1} + \lambda \\ d - r^2 + \|x\|^2 \\ s - b + Ax \end{bmatrix} + \begin{bmatrix} 2\kappa I & 0 & 0 & 2x & A^\top \\ 0 & d^{-2} & 0 & 1 & 0 \\ 0 & 0 & \text{Diag}(s^{-2}) & 0 & I \\ 2x^\top & 1 & 0 & 0 & 0 \\ A & 0 & I & 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta d \\ \Delta s \\ \Delta \kappa \\ \Delta \lambda \end{bmatrix}. \quad (11)$$

We could solve this system directly, but it is more efficient to note that the last conditions imply

$$\begin{cases} \Delta \kappa = -\kappa + d^{-1} - d^{-2} \Delta d \\ \Delta \lambda = -\lambda + s^{-1} - \text{Diag}(s^{-2}) \Delta s \\ \Delta d = -d + r^2 - \|x\|^2 - 2x^\top \Delta x \\ \Delta s = -s + b - Ax - A \Delta x \end{cases} \quad (12)$$

which means the entire Newton step can be expressed in terms of Δx . The first n equations of the Newton system (11) are thus

$$-2\kappa x - A^\top \lambda = 2\kappa \Delta x + 2x \Delta \kappa + A^\top \Delta \lambda$$

$$\begin{aligned}
 &= 2\kappa\Delta x + 2x[d^{-1} - \kappa - d^{-2}\Delta d] + A^\top[s^{-1} - \lambda - \text{Diag}(s^{-2})\Delta s] \\
 &= 2\kappa\Delta x + 2x[d^{-1} - \kappa - d^{-2}(-d + r^2 - \|x\|^2 - 2x^\top\Delta x)] \\
 &\quad + A^\top[s^{-1} - \lambda - \text{Diag}(s^{-2})(-s + b - Ax - A\Delta x)]
 \end{aligned}$$

or equivalently,

$$\left[2\kappa I + \frac{4}{d^2}xx^\top + A^\top \text{Diag}(s^{-2})A \right] \Delta x = \frac{r^2 - \|x\|^2 - 2d}{d^2}2x + A^\top \text{Diag}(s^{-2})(b - Ax - 2s). \tag{13}$$

After solving this system for Δx , we can compute the other components of the Newton step through equations (12). Now that it is clear how one can compute the Newton step for problem (7), we propose Algorithm 2 to solve (7).

Let us make a few observations about this algorithm. First, note that if $\kappa > 0$, the matrix $2\kappa I + 4d^{-2}xx^\top + A^\top \text{Diag}(s^{-2})A$ is positive definite, and hence invertible. Thus, as long as $\kappa > 0$, the system (13) will have a (unique) solution Δx .

Second, the value for t in Line 10 of Algorithm 2 is chosen such that after the update, d , s , and κ will all remain positive. In principle, the value 0.9 could be replaced by any real number from $(0, 1)$. Note that we are not requiring that λ remains positive in all iterations: numerical evidence suggests that the method is more likely to succeed if some elements of λ are allowed to be negative in some iterations. Nevertheless, Algorithm 2 only returns a success status if the final λ is nonnegative.

Third, the algorithm returns the current solution x with success status in two cases. In either case, the current solution should approximately be a stationary point of the Lagrangian, i.e. the norm of $\nabla L(x, d, s, \kappa, \lambda)$ has to be small, and we should have $\lambda \geq 0$. Moreover, one of the following conditions should hold:

1. Updating the point by adding t times the Newton step leads to a larger norm of the Lagrangian gradient. In this case, taking the step does not improve the solution. Since the current point is already approximately a stationary point, this solution is returned;

2. We are in iteration k_{\max} . Since the current point is approximately a stationary point, this solution is returned.

The reason to continue taking Newton steps even if the norm of the Lagrangian's gradient is small is that Newton's method converges very rapidly when the current point is near the optimum. By running just a few more iterations, we get a solution with much higher accuracy.

Algorithm 2 Infeasible start Newton method for (7)

Input: Convex body $\mathcal{Q} = \{x \in \mathbb{R}^n : \|x\|^2 \leq r^2, Ax \leq b\}$, where $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$; starting point $x_0 \in \mathbb{R}^n$; maximum number of iterations $j_{\max} = 50$; gradient norm tolerance $\delta = 10^{-8}$.

```

1: function ANALYTICCENTER( $\mathcal{Q}, x_0$ )
2:    $j \leftarrow 1$ 
3:    $d_0 \leftarrow \begin{cases} r^2 - \|x_0\|^2 & \text{if } r^2 - \|x_0\|^2 > 0 \\ 1 & \text{otherwise} \end{cases}$ 
4:    $(s_0)_i \leftarrow \begin{cases} b_i - a_i^\top x & \text{if } b_i - a_i^\top x > 0 \\ 1 & \text{otherwise} \end{cases}$  for all  $i = 1, \dots, m$ 
5:    $\kappa_0 \leftarrow -1$ 
6:    $\lambda_0 \leftarrow 0$ 
7:   while  $j \leq j_{\max}$  do
8:     Compute  $\Delta x_j$  from (13)
9:     Compute  $(\Delta d_j, \Delta s_j, \Delta \kappa_j, \Delta \lambda_j)$  from (12)
10:     $t_j \leftarrow \min\{1, 0.9 \times \sup\{t \geq 0 : d_j + t\Delta d_j \geq 0, s_j + t\Delta s_j \geq 0, \kappa_j + t\Delta \kappa_j \geq 0\}\}$ 
11:     $g_j(t) := \|\nabla L(x_j + t\Delta x_j, d_j + t\Delta d_j, s_j + t\Delta s_j, \kappa_j + t\Delta \kappa_j, \lambda_j + t\Delta \lambda_j)\|$ 
12:    if  $g_j(0) \leq \delta$  and  $\lambda_j \geq 0$  and  $(g_j(t_j) \geq g_j(0)$  or  $j = j_{\max})$  then
13:      return  $x_j$  with success status
14:    end if
15:     $j \leftarrow j + 1$ 
16:  end while
17:  return  $x_j$  with failure status
18: end function

```

Finally, compared to the algorithm in (Boyd et al. 2011, Section 2), Algorithm 2 does not use backtracking line search. The reason is that for problem (7), the norm of the Lagrangian gradient does not seem to decrease monotonically during the algorithm's run. In fact, the norm of this gradient usually first decreases to the order 10^0 , then increases slightly to the order 10^1 , before decreasing rapidly to the order 10^{-8} . If one does backtracking line search on t to ensure that in every iteration the norm of the gradient decreases, the values of t

can become very small (say, of the order 10^{-9}). Then, the number of iterations required to achieve convergence would be impractically large.

2.3. Pruning Constraints

The next question we should answer is how we can prune constraints from our outer approximation (5). Pruning is often used to reduce the number of constraints defining the outer approximation, which keeps the computational effort per iteration stable. Moreover, the linear system (13) will quickly become ill-conditioned if no constraints are dropped.

The idea we use is the same as in (Boyd et al. 2011, Section 3): denote the barrier of which we compute the analytic center by

$$\Phi(x) := -\log(r^2 - \|x\|^2) - \sum_{i=1}^m \log(b_i - a_i^\top x). \quad (14)$$

Since Φ is self-concordant, the Dikin ellipsoid around the analytic center of Φ is contained in \mathcal{Q} , i.e.

$$\{x \in \mathbb{R}^n : (x - x_*)^\top \nabla^2 \Phi(x_*) (x - x_*) \leq 1\} \subseteq \mathcal{Q}, \quad (15)$$

where x_* is the minimizer of Φ and

$$\nabla^2 \Phi(x_*) = \frac{2}{r^2 - \|x_*\|^2} I + \frac{4}{(r^2 - \|x_*\|^2)^2} x_* x_*^\top + \sum_{i=1}^m \frac{1}{(b_i - a_i^\top x_*)^2} a_i a_i^\top.$$

Moreover, it will be shown at the end of this section that for our outer approximation \mathcal{Q} it holds that

$$\mathcal{Q} \subseteq \{x \in \mathbb{R}^n : (x - x_*)^\top \nabla^2 \Phi(x_*) (x - x_*) \leq (m+2)^2\}. \quad (16)$$

Hence, following Boyd et al. (2011), we define the relevance measure

$$\eta_i := \frac{b_i - a_i^\top x_*}{\sqrt{a_i^\top \nabla^2 \Phi(x_*)^{-1} a_i}}, \quad (17)$$

for all linear constraints $i = 1, \dots, m$.

For any i , let us first show that $\eta_i \geq 1$. To this end, note that

$$x = x_* + \frac{1}{\sqrt{a_i^\top \nabla^2 \Phi(x_*)^{-1} a_i}} \nabla^2 \Phi(x_*)^{-1} a_i$$

lies in \mathcal{Q} by (15), and therefore $b_i \geq a_i^\top x = a_i^\top x_* + \sqrt{a_i^\top \nabla^2 \Phi(x_*)^{-1} a_i}$. Hence, $\eta_i \geq 1$ by (17).

Moreover, we can show that if $\eta_i \geq m+2$, the corresponding constraint is certainly redundant. For any $x \in \mathbb{R}^n$ such that $(x - x_*)^\top \nabla^2 \Phi(x_*) (x - x_*) \leq (m+2)^2$, we have

$$a_i^\top x = a_i^\top x_* + (\nabla^2 \Phi(x_*)^{1/2} (x - x_*))^\top (\nabla^2 \Phi(x_*)^{-1/2} a_i) \leq a_i^\top x_* + (m+2) \sqrt{a_i^\top \nabla^2 \Phi(x_*)^{-1} a_i},$$

by Cauchy-Schwarz. When $\eta_i \geq m + 2$, we therefore find that $a_i^\top x \leq b_i$. Since this inequality holds for the ellipsoid that contains \mathcal{Q} by (16), it follows that $a_i^\top x \leq b_i$ is redundant.

With this in mind, we propose Algorithm 3 to prune constraints from \mathcal{Q} . Note that the ball constraint $\|x\|^2 \leq r^2$ is never pruned.

Algorithm 3 A pruning method for the intersection of a ball and a polyhedron

Input: Convex body $\mathcal{Q} = \{x \in \mathbb{R}^n : \|x\|^2 \leq r^2, Ax \leq b\}$, where $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$;

analytic center x_* of \mathcal{Q} ; maximum number of linear inequalities $m_{\max} = 4n$.

```

1: function PRUNE( $\mathcal{Q}, x_*$ )
2:   if  $m > n$  then
3:     Compute  $\eta_i$  as in (17) for  $i = 1, \dots, m$ 
4:     Remove all constraints  $a_i^\top x \leq b_i$  with  $\eta_i \geq m + 2$  from  $\mathcal{Q}$ 
5:     if  $\mathcal{Q}$  still contains more than  $m_{\max}$  linear inequalities then
6:       Remove the constraints  $a_i^\top x \leq b_i$  with the largest values of  $\eta_i$  from  $\mathcal{Q}$  such
           that  $m_{\max}$  remain
7:     end if
8:   end if
9:   return  $\mathcal{Q}$ 
10: end function

```

As an alternative, one might consider dropping $m - m_{\max}$ constraints, possibly keeping some redundant constraints. The reason we do not adopt this strategy is that we noticed Algorithm 3 leads to slightly better numerical performance on our test sets.

We finish this section with a proof of the relation (16), which can be seen as an application of the theory by Nesterov and Nemirovskii (1994).

PROPOSITION 2. *Let $A \in \mathbb{R}^{m \times n}$ have rows $a_1^\top, \dots, a_m^\top$, and let $b \in \mathbb{R}^m$, and $r > 0$. Let \mathcal{Q} be as defined in (5), and assume that it has nonempty interior. Define Φ as in (14), and let x_* be the minimizer of Φ . Then, for any $x \in \text{dom } \Phi$, we have*

$$(x - x_*)^\top \nabla^2 \Phi(x_*)(x - x_*) \leq (m + 2)^2.$$

Proof. Define the barrier function

$$f(t, \tilde{x}, s) := -\log(t^2 - \|\tilde{x}\|^2) - \sum_{i=1}^m \log(s_i),$$

whose domain is a symmetric cone. The complexity value ϑ of f (see Section 2.3.1 in Renegar (2001)) satisfies $\vartheta \leq m + 1$. Note that any $x \in \text{dom } \Phi$ if and only if $(r, x, b - Ax) \in \text{dom } f$. We will first show that the gradient of f at $(r, x_*, b - Ax_*)$ is orthogonal to $(r, x, b - Ax) - (r, x_*, b - Ax_*) = (0, x - x_*, A(x_* - x))$. The claim will then follow from a property of symmetric cones.

The gradient of f is

$$\nabla f(t, \tilde{x}, s) := \begin{bmatrix} -2t/(t^2 - \|\tilde{x}\|^2) \\ 2x/(t^2 - \|\tilde{x}\|^2) \\ -s^{-1} \end{bmatrix},$$

so it follows that

$$\nabla f(r, x_*, b - Ax_*)^\top \begin{bmatrix} 0 \\ x - x_* \\ A(x_* - x) \end{bmatrix} = \frac{2x_*^\top(x - x_*)}{r^2 - \|x_*\|^2} - \sum_{i=1}^m \frac{a_i^\top(x_* - x)}{b_i - a_i^\top x_*}. \quad (18)$$

Because x_* is the minimizer of the convex function Φ , we have

$$0 = \nabla \Phi(x_*) = \frac{2}{r^2 - \|x_*\|^2} x_* + \sum_{i=1}^m \frac{1}{b_i - a_i^\top x_*} a_i,$$

which implies that (18) is zero. Therefore, Theorem 3.5.9 in Renegar (2001) shows that

$$\begin{bmatrix} 0 \\ x - x_* \\ A(x_* - x) \end{bmatrix}^\top \nabla^2 f(r, x_*, b - Ax_*) \begin{bmatrix} 0 \\ x - x_* \\ A(x_* - x) \end{bmatrix} \leq \vartheta^2, \quad (19)$$

where $\nabla^2 f$ is the Hessian of f , given by

$$\nabla^2 f(t, \tilde{x}, s) := \frac{1}{(t^2 - \|\tilde{x}\|^2)^2} \begin{bmatrix} 2t^2 + 2\|\tilde{x}\|^2 & -4t\tilde{x}^\top & 0 \\ -4t\tilde{x} & 2(t^2 - \|\tilde{x}\|^2)I + 4\tilde{x}\tilde{x}^\top & 0 \\ 0 & 0 & (t^2 - \|\tilde{x}\|^2)^2 \text{Diag}(s^{-2}) \end{bmatrix}.$$

In other words, (19) is equivalent to

$$(x - x_*)^\top \left[\frac{2}{r^2 - \|x_*\|^2} I + \frac{4}{(r^2 - \|x_*\|^2)^2} x_* x_*^\top \right] (x - x_*) + \sum_{i=1}^m \frac{(a_i^\top(x_* - x))^2}{(b_i - a_i^\top x_*)^2} \leq \vartheta^2,$$

which proves the claim, since $\vartheta \leq m + 2$. □

2.4. Algorithm Description

Now that we answered the major questions surrounding an ACCP method for checking complete positivity of a matrix, we move on to our final method. We start with a quite general analytic center cutting plane method, and then add a wrapper function that performs the complete positivity check. The reason for making this split is that it makes our code easy to extend when solving other copositive optimization problems for which a bound on the norm of an optimal solution is known. We state our proposed analytic center cutting plane method to solve (2) in Algorithm 4.

We continue the algorithm even if we cannot find the analytic center to high accuracy. Late in the algorithm's run, the system (13) often becomes ill-conditioned. This is to be expected, since as Algorithm 4 progresses, the outer approximation \mathcal{Q}_k becomes smaller and smaller. The distance from the analytic center to the linear constraints also goes to zero, but not at the same pace for every constraint. We may arrive in a situation where $b_i - a_i^\top x_k$ is of the order 10^{-4} for some constraints i , and of the order 10^{-8} for other constraints. This causes a considerable spread in the eigenvalues of the matrix in (13).

If the analytic center is not known to acceptable accuracy, the pruning procedure in Algorithm 3 may remove constraints that are actually very important to the definition of \mathcal{Q}_k . One could of course still run the pruning function using the inaccurate analytic center approximation. However, because the problems in the analytic center computation only occur late in the algorithm's run, pruning or not pruning with the inaccurate approximation does not seem to have a major impact on total runtime.

Algorithm 4 is a (relatively) general analytic center cutting plane method. The problem (1) can be solved by calling Algorithm 4 with appropriate parameters, as is done by Algorithm 5.

2.5. A Note on Complexity

Our aim in this paper is to propose an algorithm with good practical performance. This is why we placed emphasis on a robust copositivity check, constraint pruning, and efficient computation of the analytic center. However, such an algorithm does not lend itself well to a formal complexity analysis. For instance, to the best of the authors' knowledge, the only analysis in the literature of an analytic center cutting plane method with constraint pruning is due to Atkinson and Vaidya (1995). Although the number of constraints in their

Algorithm 4 Analytic Center Cutting Plane method to solve (2)

5:   return  $\text{smat}(\text{ACCP}(c, \text{ORACLE}, r))$ 
6: end function

```

The analysis that perhaps comes closest to covering our algorithm is the survey by Goffin and Vial (2002), who find a polynomial number of iterations for an analytic center cutting plane method with deep cuts. Their method only uses linear constraints, and does not prune cuts. Moreover, the method of recovering a feasible solution after adding a deep cut is different from the infeasible start Newton method we use.

Nevertheless, we compared our method numerically to Goffin and Vial's, and found that our method exhibits somewhat better numerical performance on our test set. In particular, Goffin and Vial's method struggles earlier to approximate the analytic center. Whereas we could solve the problems in our test set up to a relative gap of 10^{-6} , Goffin and Vial's method sometimes failed to recover a point in the feasible set when the relative gap was still of the order 10^{-5} . The condition number of their linear systems had become very large at this point, explaining the inaccuracy. At this level of the relative gap, the condition number of the system (13) in our algorithm was somewhat lower.

In short, while our method is not covered by a formal complexity analysis, we do prefer it over other algorithms in the literature for numerical reasons.

3. Numerical Experiments

3.1. Extremal Matrices of the 6×6 Doubly Nonnegative Cone

We test Algorithm 5 on extremal matrices from the doubly nonnegative cone. Ten of such 6×6 matrices were proposed in (Badenbroek and de Klerk 2019, Appendix B). We run Algorithm 5 on these matrices, and record the number of calls to TESTCOPOSITIVE. For the sake of comparison, we also applied the ellipsoid method of Yudin and Nemirovski (1976) and the volumetric center cutting plane (VCCP) method from Anstreicher (1998).

The termination criteria for these methods is similar to that in Algorithm 4, i.e. the relative gap can be at most 10^{-6} . One difference is that in the case of the ellipsoid method, the lower bound is computed through minimization over the current ellipsoid, not over some outer approximation \mathcal{Q} .

One should however be careful when comparing the VCCP method with Algorithm 5 and the ellipsoid method. While Algorithm 4 maintains the intersection of a unit ball and a polytope as an outer approximation, the VCCP method maintains a polytope. We start the VCCP method with the hypercube $[-1, 1]^n$ as an outer approximation, which is larger than the unit ball. This difference also means that it would be meaningless to compare the objective value returned by the VCCP method to those returned by Algorithm 5 or the ellipsoid method, which is why we do not report the former.

A second reason to be wary when comparing these methods is that, in our implementation, the VCCP method sometimes suffered from ill-conditioning that caused it to crash. (The vector σ in Anstreicher (1998) is supposed to remain elementwise positive. Through numerical errors, this vector could contain negative elements late in the VCCP method's run.) We have indicated instances where this occurred with an asterisk in Table 1. This table records the final objective value for all instances for Algorithm 5 and the ellipsoid method, as well as the number of calls to `TESTCOPOSITIVE` for all three methods.

The reason to report this number of calls is that the oracle performs the theoretically intractable part of these methods: testing if a matrix is copositive. All other parts of the considered methods complete in polynomial time for each oracle call. Hence, to get the best performance for larger matrices, one would like to minimize the number of oracle calls.

As can be seen from Table 1, both Algorithm 5 and the ellipsoid method manage to find deep cuts that separate the matrices from the completely positive cone. (The same in fact holds for the VCCP method.) However, Algorithm 5 does this with roughly 50 times fewer calls to the copositivity oracle than the ellipsoid method. The number of oracle calls used by the VCCP method is of the same order of magnitude as that of Algorithm 5. However, it appears to suffer more from numerical instabilities than Algorithm 5.

3.2. Matrices on the Boundary of the Doubly Nonnegative Cone in Higher Dimensions

To investigate how Algorithm 5 scales, we also generated test instances in higher dimensions. To the best of our knowledge, a complete characterization of the extremal rays of

* Did not terminate successfully due to numerical issues

the $d \times d$ doubly nonnegative cone is unknown for $d > 6$. (See the corollary to Theorem 3.1, and Propositions 5.1 and 6.1 in Ycart (1982) for the extremal matrices for $d \leq 6$.) Hence, we use a semidefinite programming heuristic to find doubly nonnegative matrices in these dimensions which are not completely positive.

The matrices used in Section 3.1 are 6×6 doubly nonnegative matrices C with rank 3 and the entries $C_{i,i+1} = 0$ for all $i \in \{1, \dots, 5\}$. This pattern of zeros can of course be extended to higher dimensions, but the low rank criterion is not tractable in semidefinite programming. The standard trick to find a low-rank solution – which we also adopt – is to minimize the trace of the matrix variable, see e.g. Fazel et al. (2001) and the references therein. To create a $d \times d$ test instance, we thus run the procedure in Algorithm 6.

The objective in Line 3 of Algorithm 6 includes two terms: the term $\text{tr} C$ to get a low-rank solution, and the term $\frac{1}{2}d\|C - R\|$ to get a solution close to our random matrix R . Without this last term, the optimal solution of the problem would be the zero matrix. The weight $\frac{1}{2}d$ was chosen because numerical experiments suggested this weight leads to solutions with low rank, but not rank zero, for the dimensions in our test set. The solution C^* computed in Line 3 by interior point methods still lies in the interior of the doubly nonnegative cone. To project this solution to the boundary of the doubly nonnegative cone, we run the Lines 4 to 7.

For each $d \in \{6, 7, 8, 9, 10, 15, 20, 25\}$, we generated ten test instances with Algorithm 6. Such an instance C is only included in the final test set if Algorithm 5 returns an X such that $\langle C, X \rangle < -0.01$, which was almost always the case. In those

Algorithm 6 A heuristic procedure to generate random matrices on the boundary of the doubly nonnegative cone

-

few cases where $\langle C, X \rangle \geq -0.01$, a new instance was generated. Hence, we end up with ten $d \times d$ doubly nonnegative matrices that are not completely positive, for each $d \in \{6, 7, 8, 9, 10, 15, 20, 25\}$. These instances are available at <https://github.com/rileybadenbroek/CopositiveAnalyticCenter.jl/tree/master/test>.

Algorithm 5 is applied to each of these instances, and the total number of calls to TESTCOPOSITIVE is reported in Figure 1. (We do not report these results as in Table 1 since there are 80 instances, and running the ellipsoid method for all of them would take too much time.) As one can see, the number of oracle calls for one of our test instances with dimension d is roughly $7d^{5/3}$.

4. Conclusion and Future Research

We have proposed an analytic center cutting plane algorithm to separate a matrix from the completely positive cone. This algorithm solves an optimization problem over the copositive cone, where membership of the copositive cone is tested through a mixed-integer linear program. We have emphasized stable numerical performance, which leads to an algorithm for which we do not have a formal complexity analysis. On the other hand, the

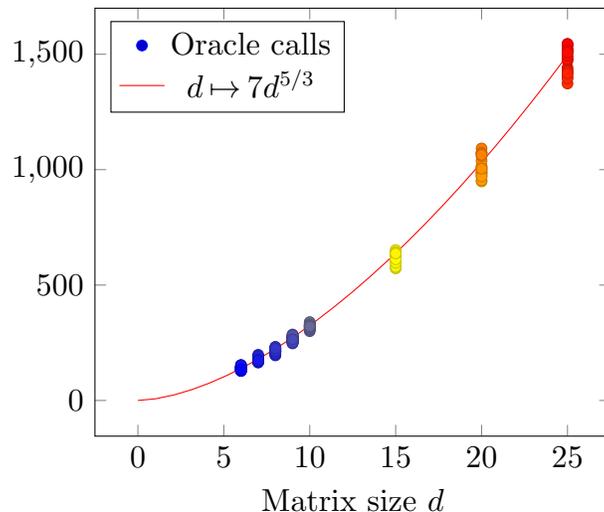

Figure 1 Number of oracle calls in Algorithm 5 for the $d \times d$ test instances generated with Algorithm 6.

numerical results are encouraging. In particular, the number of oracle calls to test matrix copositivity grows roughly like $O(d^2)$ for $d \times d$ matrices. Thus one can leverage the recent progress on testing matrix copositivity from Badenbroek and de Klerk (2019) or the similar methods by Anstreicher (2020) and Gondzio and Yildirim (2018). We have therefore made some computational progress on an open problem formulated by Berman et al. (2015). It is worthwhile to note that our algorithm can be applied to any copositive optimization problem, as long as an upper bound on the norm of the optimal solution is known. The code is available at <https://github.com/rileybadenbroek/CopositiveAnalyticCenter.jl>.

Future research could compare the copositivity test we use with other recent proposals, such as the aforementioned Anstreicher (2020) and Gondzio and Yildirim (2018). The latter paper in particular shows promising performance compared to Xia et al. (2018), which formed the basis of our copositivity test.

Moreover, following (Anstreicher et al. 2012, Theorem 3), one could use the cuts from a method like ours to factorize a completely positive $C \in \mathbb{S}^d$ as $C = BB^\top$ for some $B \geq 0$. Suppose we added the cuts $X \mapsto y_k^\top X y_k \geq 0, k = 1, \dots, K$ during our algorithm's run to separate iterates from \mathcal{COP}^d , where $y_k \geq 0$ for all k (see Line 7 in Algorithm 1). If $\min_X \{ \langle C, X \rangle : y_k^\top X y_k \geq 0 \forall k = 1, \dots, K \} = 0$, it follows that C must lie in the dual of the polyhedral cone that is the intersection of these cuts. Consequently, C can be written as $C = \sum_{k=1}^K u_k y_k y_k^\top$ for some $u_k \geq 0, k = 1, \dots, K$. Finding a completely positive factorization of C then amounts to solving a linear program. It remains to be seen if this strategy is viable in practice.

Acknowledgments

We are grateful to two anonymous referees for their thoughtful comments, and for providing useful references to the literature. We would moreover like to thank François Glineur for pointing out a mistake in an earlier version of this work, and Alper Yıldırım for pointing out the reference Gondzio and Yıldırım (2018).
